Clinical signs and special examination

A general clinical examination is followed by a special examination of the skin and must include inspection and, in most cases, palpation. Additional information can be obtained by taking swabs for bacteriological examinations, scrapings for examination for dermatophytes and metazoan parasites, and biopsy for histopathological examination.

Biopsy material should include abnormal, marginal, and normal skin. Artifacts are common in biopsy specimens, including nonrepresentative sampling, crushing the specimen by forceps or hemostat, and inadequate fixation.

Wood's lamp finds a special use in the examination of the skin for dermatophytes. Descriptions of lesions should include size, depth to which they penetrate, geographical distribution on the body and size of the area covered. Abnormalities of sebaceous and sweat secretion, changes in the hair or wool coat and alterations in color of the skin should be noted, as should the presence or absence of pain or itching.
Pruritus and the manifestations of skin disease and the common lesions defined below.

**Lesions**
An accurate definition of the lesions, summarized in Table 14.1, is an essential part of a skin patient’s clinical record. The table makes a primary differentiation into discrete and diffuse lesions and these categories need to be further categorized in terms of size, e.g. they may be limited diffuse lesions or extensive localized ones.

**Abnormal coloration**
This parameter includes jaundice, pallor and erythma, and these are best seen in the oral or vaginal mucosa or in the conjunctiva. In animals they are rarely visible in light-colored skins. Red-purple discoloration of the skin of septicemic, white pigs may be dramatic but no diagnostic significance can be attached to its degree. Early erythema is a common finding where more definite skin lesions are to develop, as in early photosensitization. The blue coloration of early gangrene (c.g. of the udder and teat skin in the early stages of peracute bovine mastitis associated with *Staphylococcus aureus*) is characterized by coldness and loss of elasticity.

Hypopigmentation of the skin may be general, as in albino, pseudoalbino and lethal white animals. Local patches of hypopigmentation are characteristic of vitiligo and leukoderma.

**Pruritus**
- **Pruritus or itching** is the sensation that gives rise to scratching

All sensations that give rise to rubbing or scratching are therefore included with pruritus, more properly defined as scratching. Pruritus can arise from peripheral or central stimulation. When it is peripheral in origin it is a primary cutaneous sensation like heat, cold, pain and touch; it differs from pain because it is purely epidermal, whereas pain can still be felt in areas of skin denuded of epidermis. Thus itching does not occur in the center of deep ulcerations nor in very superficial lesions, such as those of ringworm, where only the hair fibers

</table>

1. Above skin, usually all
2. Pyoderma is any infection of skin; includes impetigo, acne, pustule, pimple
and keratinized epithelium are involved. Itching can be elicited over the entire skin surface but is most severe at the mucocutaneous junctions. Common causes include the following:

**Cattle**
- Sarcoptic and chorioptic mange
- Aujeszky's disease
- Nervous acetonemia
- Lice infestation.

**Sheep**
- Lice, mange, ked, blowfly and itch-mite infestations
- Scrapie.

**Pigs**
- Sarcoptic and chorioptic mange
- Lice infestation.

**Horses**
- Chorioptic mange on the legs
- Queensland (sweet) itch along the dorsum of the body
- Lice infestation
- Perianal pruritus due to *Oxyuris equi* infestation.

All species
- The early stages of photosensitive dermatitis
- Urticarial wheals in an allergic reaction
- ‘Licking syndromes’ such as occur in cattle on copper-deficient diets are accompanied by pica and the licking of others as well as themselves. They are examples of depraved appetites developed in response to nutritional deficiency and are not a response to pruritus
- Itching of central origin derives in the main from the scratch center below the acoustic nucleus in the medulla. It may have a structural basis, as in scrapie and pseudobabies, or it may be functional in origin, as in the nervous form of acetonemia. The only lesions observed are those of a traumatic dermatitis with removal of the superficial layers to a variable depth, breakage or removal of the hairs and a distribution of lesions in places where the animal can bite or rub easily.

**Secretion abnormalities of skin glands**

The activity of the sweat glands is controlled by the sympathetic nervous system and is for the most part a reflection of body temperature. Excitement and pain may cause sweating due to cerebral cortical activity. A generalized form of hyperhidrosis, apparently inherited, has been recorded in Shorthorn calves. Local areas of increased or decreased sweating may arise from peripheral nerve lesions or obstruction of sweat gland ducts. A generalized anhidrosis is recorded in horses and occasionally in cattle.

Excess secretion of sebum by sebaceous glands causes oiliness of the skin or seborrhea but its pathogenesis is poorly understood.

**Abnormalities of wool and hair fibers**

Deficiency of hair or wool in comparison to the normal pilosity of the skin area is **alopecia** or **hypotrichosis**.

**Hirsutism**, abnormal hairiness, manifested by a long, shaggy, usually curly, coat is most common in aged ponies with adenomas of the pars intermedia of the pituitary gland.

The character of the fiber may also vary with variations in the internal environment. For example, in copper deficiency the crimp of fine wool fibers is lost and the wool becomes straight and 'steely'. Alternation in coat color, achromotrichia, may be generalized or segmental along the fiber.

**Principles of treatment of diseases of the skin**

**PRIMARY TREATMENT**

Primary treatment commences with removal of hair coat and debris to enable topical applications to come into contact with the causative agent. Accurate diagnosis of the cause must precede the selection of any topical or systemic treatment. In bacterial diseases sensitivity tests on cultures of the organism are advisable. Specific skin diseases due to bacteria, fungi and metazoan parasites are reasonably amenable to treatment with the appropriate specific remedy.

Bacterial resistance to antimicrobials used in veterinary dermatological practice is a concern. The broad application of antimicrobials for various therapeutic and nontherapeutic purposes has accelerated the spread of pre-existing resistance genes and led to the apparent development of mechanisms by which resistance genes are spread, not only within a bacterial species, but also between bacterial species. Every veterinarian must strive to practice prudent use of antimicrobials in order to minimize the resistance problem.

Removal of the causative agent in allergic diseases and photosensitization may be impossible and symptomatic treatment may be the only practicable solution. In many cases, too, the primary disease may be confounded by the presence of a secondary agent, which can lead to confusion in diagnosis. Treatment may be unsuccessful if both agents are not treated.

**SUPPORTIVE TREATMENT**

Supportive treatment includes prevention of secondary infection by the use of bacteriostatic ointments or dressings and the prevention of further damage from scratching.

- Effective treatment of pruritus depends upon the reduction of central perception of itch sensations by the use of antihistamines, sedative or narcotic drugs administered systemically or on successful restraint of the mediator between the lesion and the sensory end organ. In the absence of accurate knowledge of the pathogenesis of pain it is usual to resort to local anesthetic agents, which are shortlived in their activity, and corticosteroids, which are longer-acting and effective, provided that vascular engorgement is part of the pruritus-stimulating mechanism.

When large areas of skin are involved it is important to prevent the absorption of toxic products by continuous irrigation or the application of absorptive dressings. Losses of fluid and electrolytes should be made good by the parenteral administration of isotonic fluids containing the necessary electrolytes. Ensure an adequate dietary intake of protein, particularly sulfur-containing amino acids to facilitate the repair of skin tissues.

- Boredom contributes significantly to an animal's response to itch stimuli, and close confinement of affected animals is best avoided.

**REFERENCE**

Diseases of the epidermis and dermis

PITYRIASIS

Primary pityriasis, excessive bran-like scales on the skin, characterized by overproduction of keratinized epithelial cells, can be caused by:
- Hypovitaminosis A
- Nutritional deficiency of B vitamins, especially of riboflavin and nicotinic acid, in pigs, or linolenic acid, and probably other essential unsaturated fatty acids
- Poisoning by iodine
- Pityriasis rosea occurs in humans and pigs and the etiology is unknown. The literature for and against an infectious etiology has been reviewed.

Secondary pityriasis, characterized by excessive desquamation of epithelial cells is usually associated with:
- Scratching in flea, louse and mange infestations
- Keratolytic infection, e.g. with ringworm fungus

Pityriasis scales are accumulations of keratinized epithelial cells, sometimes softened and made greasy by the exudation of serum or sebum. Overproduction, when it occurs, begins around the orifices of the primary disease.

TREATMENT
Primary treatment requires correction of any nutritional deficiency.

Supportive treatment includes removal of the crusts by the use of keratolytic agent (e.g. salicylic acid ointment) or by vigorous scrubbing with soapy water, followed by application of an astrigent (e.g. white lotion paste), which must be applied frequently and for some time after the lesions have disappeared.

PARAKERATOSIS

Parakeratosis, a skin condition characterized by incomplete keratinization of epithelial cells, can be:
- Caused by nonspecific chronic inflammation of cellular epidermis
- Associated with dietary deficiency of zinc
- Part of an inherited disease listed below.

The initial lesion comprises edema of the prickle cell layer, dilatation of the intercellular lymphatics, and leukocyte infiltration. Imperfect keratinization of epithelial cells at the granular layer of the epidermis follows, and the horn cells produced are sticky and soft, retain their nuclei and stick together to form large masses, which stay fixed to the underlying tissues or are shed as thick scales.

The lesions may be extensive and diffuse but are often confined to the flexor aspects of joints (referred historically in horses as mallenders and sallenders). Initially the skin is reddened, followed by thickening and gray discoloration. Large, soft scales accumulate, are often held in place by hairs and usually crack and fissure, and their removal leaves a raw, red surface. Hyperkeratosis scales are thin, dry and accompany an intact, normal skin.

Confirmation of a diagnosis of parakeratosis is by the identification of imperfect keratinization in a histopathological examination of a biopsy or a skin section at necropsy.

DIFFERENTIAL DIAGNOSIS
- Hyperkeratosis (see below)
- Parakeratosis (see below)

TREATMENT
Primary treatment requires removal of the causal irritation but in well-established cases and includes removal of the crusts by the use of keratolytic agent (e.g. salicylic acid ointment) or by vigorous scrubbing with soapy water, followed by application of an astrigent (e.g. white lotion paste), which must be applied frequently and for some time after the lesions have disappeared.

PACHYDERMA

Pachyderma, including scleroderma, is thickening of the skin affecting all layers, often including subcutaneous tissue, and usually localized but often extensive as in lymphangitis and greasy heel in horses. There are no specific causes, most cases being due to nonspecific chronic or recurrent inflammation.

In affected areas the hair coat is thin or absent and the skin is thicker and tougher than usual. It appears tight and, because of its thickness and reduced volume of subcutaneous tissue, cannot be picked into folds or moved easily over underlying tissue. The skin surface is unbroken and there are no lesions and no crusts or scabs as in parakeratosis and hyperkeratosis (see above).

Confirmation of the diagnosis depends on histopathological examination of a biopsy. The cells in all layers are usually normal but the individual layers are increased in thickness. There is hypertrophy of the prickle cell layer of the epidermis and enlargement of the inter-papillary processes.

DIFFERENTIAL DIAGNOSIS
- Parakeratosis (see above)
- Cutaneous neoplasia
- Papillomatosis

TREATMENT
Primary treatment requires removal of the causal irritation but in well-established cases and includes removal of the crusts by the use of keratolytic agent (e.g. salicylic acid ointment) or by vigorous scrubbing with soapy water, followed by application of an astrigent (e.g. white lotion paste), which must be applied frequently and for some time after the lesions have disappeared.

HYPERKERATOSIS

Epithelial cells accumulate on the skin as a result of excessive keratinization of epithelial cells and intercellular bridges, interference with normal cell division in the granular layer of the epidermis and hypertrophy of the stratum corneum.

Lesions may be local at pressure points, e.g. elbows, when animals lie habitually on hard surfaces. Generalized hyperkeratosis may be caused by:
- Poisoning with highly chlorinated naphthalene compounds
- Chronic arsenic poisoning
- Inherited congenital ichthyosis
- Inherited dyskeratosis–dyskeratosis

The skin is dry, scaly, thicker than normal, usually corrugated, hairless and fissured in a gridlike pattern. Secondary infection of deep fissures may occur if the area is continually wet. However, the lesion is usually dry and the plugs of hyperkeratotic material can be removed, leaving the underlying skin intact.

Confirmation of the diagnosis is by the demonstration of characteristically thickened stratum corneum in a biopsy section, which also serves to differentiate the condition from parakeratosis (see below) and inherited ichthyosis.

Primary treatment depends on correction of the cause. Supportive treatment is by the application of a keratolytic agent (e.g. salicylic acid ointment).

DIFFERENTIAL DIAGNOSIS
- Hyperkeratosis (see above)
- Pachyderma (see below)
- Ringworm
- Inherited ichthyosis
- Inherited Adema disease in cattle
- Inherited dermatosis vegetans in pigs
- Inherited epidermal dysplasia
cases little improvement can be anticipated, and surgical removal may be a practical solution when the area is small. In early cases local or systemic corticosteroids may effect a recovery.

**IMPETIGO**

A superficial eruption of thin-walled, small vesicles, surrounded by a zone of erythema, that develop into pustules, then rupture to form scabs.

In humans, impetigo is specifically a streptococcal infection but lesions are often invaded secondarily by staphylococci. In animals the main organism found is usually a staphylococcus. The causative organism appears to gain entry through minor abrasions, with spread resulting from rupture of lesions causing contamination of surrounding skin and the development of secondary lesions. Spread from animal to animal occurs readily.

The only specific examples of impetigo in large animals are:

- Udder impetigo of cows
- Infectious dermatis or 'contagious pyoderma' of baby pigs associated with unspecified streptococci and staphylococci.

Small (3–6 mm) vesicles appear chiefly on the relatively hairless parts of the body and do not become confluent. In the early stages each vesicle is surrounded by a narrow zone of erythema. No irritation is evident. Vesicle rupture occurs readily but some persist as yellow scabs. Involvement of hair follicles is common and leads to the development of acne and deeper, more extensive lesions. Individual lesions heal rapidly in about a week but successive crops of vesicles may prolong the duration of the disease.

Confirmation of the diagnosis is by culture of vesicular fluid and identification of the causative bacterium and its sensitivity.

**DIFFERENTIAL DIAGNOSIS**

- Cowpox, in which the lesions occur almost exclusively on the teats and pass through the characteristic stages of pox
- Pseudocowpox, in which lesions are characteristic and also restricted in occurrence to the teats.

**TREATMENT**

Primary treatment with antibiotic topically is usually all that is required because individual lesions heal so rapidly.

Supportive treatment is aimed at preventing the occurrence of secondary lesions and spread of the disease to other animals. Twice daily bathing with an efficient germicidal skin wash is usually adequate.

**URTICARIA**

An allergic condition characterized by cutaneous wheals. It is most common in horses. 

**ETIOLOGY**

Primary urticaria results directly from the effect of the pathogen, e.g.:

- Insect stings
- Contact with stinging plants
- Ingestion of unusual food, with the allergen, usually a protein
- Occasionally an unusual feed item, e.g. garlic to a horse
- After a recent change of diet
- Administration of a particular drug, e.g. penicillin; possibly guaifenesin or other anesthetic agent
- Allergic reaction in cattle 8 days following vaccination for foot-and-mouth disease
- Death of warble fly larvae in tissue
- Milk allergy when Jersey cows are dried off
- Transfusion reaction.

Secondary urticaria occurs as part of a syndrome, e.g.:

- Respiratory tract infections in horses, including strangles and the upper respiratory tract viral infections
- Erysipelas in pigs.

**PATHOGENESIS**

The lesions are characteristic of an allergic reaction. There is degranulation of mast cells followed by liberation of chemical mediators inflammation, resulting in the subsequent development of dermal edema. A primary dilatation of capillaries causes cutaneous erythema. Edema from the damaged capillary walls causes local edema in the dermis and a wheal develops. Only the dermis, and sometimes the epidermis, is involved. In extreme cases the wheals may expand to become seromas, when they may ulcerate and discharge. The lesions of urticaria usually resolve in 12–24 hours but in recurrent urticaria an affected horse may have persistent and chronic eruption of lesions over a period of days or months. 

**CLINICAL FINDINGS**

Wheals, mostly circular, well delineated, steep-sided, easily visible elevations in the skin, appear very rapidly and often in large numbers, commencing usually on the neck but being most numerous on the body. They vary from 0.5–5 cm in diameter, with a flat top, and are tense to the touch. There is often no itching, except with plant or insect stings, nor discontinuity of the epithelial surface, exudation or weeping. Pallor of the skin in wheals can be observed only in unpigmented skin. Other allergic phenomena, including diarrhea and slight fever, may accompany the eruption. The onset of the lesions is acute to peracute with the wheals developing within minutes to hours after exposure to the triggering agent. When associated with severe adverse systemic responses, including anaphylaxis, the production of a continuous wheal following the pattern of a blunt-pointed instrument drawn across the skin, can be demonstrated about 30 minutes later.

Urticaria lasting 8 weeks or longer is classified as chronic or recurrent urticaria, which may require testing for atopic disease using intradermal skin testing and serum testing for antigen-specific IgE.

Adverse reactions in dairy cattle following annual vaccination for foot-and-mouth disease are characterized by wheals (3–20 mm in diameter) covering most of the body, followed by exudative and necrotic dermatitis. The affected areas become hairless and the wheals exude serum and become scabbed over. Edema of the legs is common and vesicles occur on the teats. The lesions appear 8–12 weeks postvaccination and may persist for 3–5 weeks. Loss of body weight and lymphadenopathy also occur. Pruritus, depression and a drop in milk yield are common.

**CLINICAL PATHOLOGY**

Intradermal skin tests to detect the presence of hypersensitivity are of little value because many normal horses, as well as those with urticaria, will respond positively to injected or topically applied allergens. Also, reactions usually occur within the first 24 hours after the injection, but the interval is very erratic. The duration of the reaction also varies a great deal. Intradermal tests in horses without atopy and horses with atopic dermatitis or recurrent urticaria using environmental allergens indicate a greater number of positive reactions for intradermal tests in horses with atopic dermatitis or recurrent urticaria, compared with horses without atopy. This provides evidence of type-I IgE-mediated hypersensitivity for these diseases.

Biopsies show that tissue histamine levels are increased and there is a local accumulation of eosinophils. Blood histamine levels and eosinophil counts may also show transient elevation.
DIFFERENTIAL DIAGNOSIS

Urticaria is manifested by a sudden appearance of a crop of cutaneous wheals, sometimes accompanied by restlessness, mostly in horses, occasionally in cattle. Identification of the etiology is also helpful in diagnosis but is often difficult, depending on a carefully taken history and examination of the environment. The differential diagnosis list is limited to angioedema, but in urticaria the lesions can be palpated in the skin itself. Angioedema involves the subcutaneous tissue rather than the skin and the lesions are much larger and more diffuse. The two conditions may appear in the one animal at the one time.

TREATMENT
Primary treatment
A change of diet and environment, especially exposure to the causal insects or plants, is standard practice. Spontaneous recovery is common.

Supportive treatment Corticosteroids, antihistamines, or epinephrine by parenteral injection provide the best and most rational treatment, especially in the relief of the pruritus, which can be annoying in some cases. One treatment is usually sufficient but lesions may recur. The local application of cooling astringent lotions such as calamine or white lotion or a dilute solution of sodium bicarbonate is favored. In large animal practice parenteral injections of calcium salts are used with apparently good results.

Long-term medical management of persistent urticaria involves the administration of corticosteroids and or antihistamines. Oral administration or prednisone or prednisolone at the lowest possible dose on alternate days is the method of choice. The antihistamine of choice is oral hydroxyzine hydrochloride initially at 600 mg three times daily, followed by gradual reduction to a minimum maintenance dose required to keep the horse free of lesions.

REFERENCES

Dermatitis and Dermatosis

Synopsis

Etiology Any disease of skin, including those characterized by inflammation. All pathogens, infectious, chemical, physical, allergic, autoimmune

Epidemiology Sporadic or outbreak, acute or chronic course, cosmetic to lethal, but of most importance as constraints on movement, sale or exhibition

Clinical signs Primarily localized to skin, including lesions varying from parakeratosis and pachyderma to weeping, through necrosis, vesicles and edema. Secondary signs of shock, toxemia, anaphylaxis

Clinical pathology Positive findings in the area of skin swabs or scrapings

Necropsy lesions Inflammatory, degenerative or vascular lesions in skin biopsy

Diagnostic confirmation Positive finding in skin biopsy

Treatment primary is removal of the pathogen; supportive includes treatment for shock, toxemia or fluid and electrolyte loss

Etiology

Some of the identifiable occurrences of dermatitis in food animals and horses are as follows.

All species
- Mycotic dermatitis due to Dermatophilus congolensis, in horses, cattle, sheep
- Staphylococcus aureus is a common finding in cases in all species, either as a sole pathogen or combined with other agents
- Ringworm
- Photosensitive dermatitis
- Chemical irritation (contact dermatitis) topically
- Arsenic – systemic poisoning
- Mange mite infestation – sarcoptic, psoroptic, chorioptic, demodicetic mange
- Trombidiiform mite infestation (tyroglyphosis)
- Biting flies especially Culicoides spp. Observed most commonly in horses, but also in other species
- Stephanofilaria sp. dermatitis
- Strongyloides (Pedlera) sp. dermatitis
- Infection with the protozoan Besnoitia spp.

Cattle
- Udder impetigo – S. aureus
- Cutaneous botryomycosis of the udder caused by a combination of trauma and infection by Pseudomonas aeruginosa
- Cowpox
- Ulcerative mamillitis – udder and teats only
- Lumpy skin disease – Allerton and Neethling ‘strains’
- Foot-and-mouth disease – vesicles around natural orifices; vesicular stomatitis with lesions on teats and coronet
- Rinderpest, bovine virus diarrhea, bovine malignant catarrh, bluetongue – erosive lesions around natural orifices, eyes, coronets
- Sweating sickness
- Perianal vesicular and necrotic dermatitis associated with mushroom poisoning
- Dermatitis on legs – potato poisoning topical application of irritants or defatting agents, e.g. diesel oil
- Dermatitis due to the ingestion of Vicia villosa and Vicia dasycarpa
- Plaque-like and cracked skin lesions on the udder, hindquarters, lips and muzzle of cattle bedded on straw
- Heavy contamination with Fusarium sporotrichioides
- Fleural seborrhea
- Bovine exfoliative dermatitis (see below)
- Slurry heel (see below).

Sheep and goats
- Strawberry footrot – Dermatophilus pedis
- Sheep pox
- Contagious ecthyma
- Ulcerative dermatosis
- Rinderpest, peste de petits ruminants, bluetongue – as for cattle
- Foot-and-mouth disease and vesicular stomatitis
- Fleece rot – constant wetting and associated with P. aeruginosa
- Lumpy wool – D. congolensis
- Itch-mite (Psoroptes ovatus) infestation
- Blowfly infestation (cutaneous myiasis)
- ‘Cockle’ (probably related to loose infestation)
- Elaeophorosis (Elaeophora sp. infestation)
- Ovine atopic dermatitis
- Caprine idiopathic dermatitis
- Postdipping necrotic dermatitis (see below).

Porcine dermatoses
- Porcine necrotic ear syndrome
- Non-specific nutritional dermatitis – experimental nutritional deficiency of

Pigs
- Ulcerative granuloma – Borrelia suilla
- Exudative epidermitis – Staphylococcus hyicus (greasy pig disease)
- Pig pox
- Swine vesicular disease, vesicular exanthema of swine, foot-and-mouth disease – vesicles around natural orifices
- Contact with fresh parsnip tops, celery
- Sunburn
- Porcine necrotic ear syndrome
- Non-specific nutritional dermatitis – experimental nutritional deficiency of

REFERENCES
The deeper layers of the skin involving the under, the bovine muzzle and coronet, causes cellular damage, often to the point of necrosis, and, depending on the type of agent responsible, the resulting dermatitis varies in its manifestations. It may be acute or chronic, supplicative, weeping, seborrheic, ulcerative or gangrenous. In all cases there is increased thickness and increased temperature of the part. Pain or itching is present and erythema is evident in unpigmented skin. Histologically there is vasodilatation and infiltration with leukocytes and cellular necrosis. These changes are much less marked in chronic dermatitis.

**CLINICAL FINDINGS**

Affected skin areas first show erythema and increased warmth. The subsequent stages vary according to the type and severity of the causative agent. There may be development of discrete vascular lesions or diffuse weeping. Edema of the skin and subcutaneous tissues may occur in severe cases. The next stage may be the healing stage of scab formation or, if the injury is more severe, there may be necrosis or even gangrene of the affected skin area. Spread of infection to subcutaneous tissues may result in a diffuse cellulitis or phlegmonous lesion. A distinct supplicative lesion is usually classified as pyoderma. Deep lesions which cause damage to dermal collagen may cause focal scarring and idiopathic fibrosing dermatitis (see below).

A systemic reaction is likely to occur when the affected skin area is extensive. Shock, with peripheral circulatory failure, may be present in the early stages. Toxemia, due to absorption of tissue breakdown products, or septicemia due to invasion via unprotected tissues, may occur in the later stages.

Individual dermatitis are as follows:

- **Bovine exfoliative dermatitis** in calves associated with the excretion of an unidentified agent in the dam’s milk. The calves show a widespread dermatitis, including vesicles on the muzzle, scaling and hair loss, at a few days of age but recover spontaneously before 3 months of age. The dam has the same disease in a mild but chronic form.

- **Bovine postdipping necrotic dermatitis** is associated with...
to handle, and the presence of the lesions under harness, where they commonly are, prevents the horse from working kindly. Harness horses are at a particular disadvantage. Individual lesions are raised nodules, 3–5 mm diameter, covered by a small, easily removed scab. When these lift they take a tuft of hair with them and a small crater is left. A little pus exudes and only a red serous fluid can be expressed. Individual lesions last a long time, at least several weeks, and fresh crops occur, causing the disease to spread slowly on the animal.

- **Chronic equine eosinophilic dermatitis** is characterized by marked acanthosis and hyperkeratosis, and eosinophilic granulomas in pancreas, salivary glands and other epithelial organs. The systemic involvement is accompanied by severe weight loss. The disease is chronic, and the cause unknown.

- **Spongiotic vesicular dermatitis** has been described in horses. Lesions are characterized by a multifocal, exudative, oozing dermatitis characterized histologically by epidermal spongiotic vesicles and perivascular eosinophilic, neutrophilic and mixed mononuclear inflammation. Some horses are pruritic.

- **Equine nodular necrobiotic**: Firm, small (up to 1 cm diameter) nodules, usually a number of them, occur on the sides of the trunk and neck. The cause is unknown. The lesions consist largely of an accumulation of eosinophils.

- **Molluscum contagiosum** is a chronic, progressive dermatitis characterized by raised, hairless lesions 0.5–2 cm in diameter, covered by soft keratin, that bleed profusely when the horse is groomed. The lesions are on the face, shoulders, trunk, lateral aspects of limbs, fetlocks and pasterns. Histological examination identifies the disease because of the presence of characteristic inclusion in cells. These are thought to be pox virus virions, but the virus cannot be cultivated from the lesions. There is no specific treatment.

- **Systemic lupus erythematosus** (SLE) is an extensive dermatitis, manifested as a scaly, crusty dermatitis of the face, neck and trunk, with loss of hair over the lesions, edema of the limbs and a mild to moderate lymph node enlargement. Multiple ulcers 11 cm in diameter are present on the oral mucosa, especially the mucocutaneous junctions of the lips and nares, and on the tongue. There is a severe systemic reaction, including a marked loss of body weight, a temperature up to 39.5°C, heart rate 80/min, respiratory rate up to 60/min, painful swollen joints containing sterile serous fluid, stiff gait, reluctance to move, and persistent lateral recumbency. SLE is an immune-mediated disease with a characteristic histopathology including a necrotizing, lymphocytic dermatitis and focal accumulations of lymphocytes in the liver, membranous glomerulonephritis and synovioctye hyperplasia. An antinuclear antibody test is diagnostic. No treatment is effective and the disease runs a chronic progressive course marked by remissions and exacerbations.

- **Discoid lupus erythematosus** is an uncommon, benign variant of the systemic disease, with cutaneous lesions similar to those in the major disease but with no involvement of other tissues.

- **Erythema multiforme** is a self-limiting skin disease of horses and cattle characterized by macular, papular, urticarial or bullous skin lesions but without any abnormality of the epidermis or loss of hair, and with no apparent itching or pain. The lesions occur symmetrically on most parts of the body, persist for long periods and increase in size up to 4–5 cm to form annular or crescent-shaped wheals. Spontaneous disappearance of the lesions after about 3 months is usual. Symptomatic treatment may be effective but is not usually necessary.

- **Equine ear plaque**: Multiple white plaques, resembling papilloma and about 1 cm in diameter, develop on the inner surface of the ear pinna of horses.

- **Equine tropical lichen** is an intensely irritating, papular eruption in the skin on the side of the neck, under the mane, the shoulders and at the tail head, occurring in summer and recurring annually. The disease closely resembles the cutaneous sensitivity to Culicoides spp. but responds dramatically to treatment with ivermectin. Microfilariae, thought to be Onchocerca spp., can be found in histological sections.

- **Linear keratosis** is most common in horses, especially Quarter horses. One case has been recorded in cattle. Lesions appear spontaneously in horses 1–5 years old and persist, usually for life. They appear first as isolated scaly lumps, which then coalesce to form a ridge, usually vertical, 3–4 cm wide and up to 70 cm long, of hyperkeratotic, hairless skin. There may be one or more lesions, commonly on the sides of the neck and chest. Symptomatic treatment appears to have no effect on the lesions.

- **Idiopathic fibrosing dermatitis**. The end stage of several severe dermatoses, this causes damage to dermal collagen. Manifested by multiple fibrous plaques in the skin caused by sclerosis of the skin or subcutis, it resembles human morbhea vulgaris and the skin granulomas of animals.

**Pemphigus**

This is an autoimmune disease of the skin, sometimes affecting mucousa and characterized by the presence of vesicles or bullae, which are usually very difficult to find, and subsequent erosions and ulcerations. There are a number of manifestations, including pemphigus vulgaris, bullous pemphigoid and pemphigus foliaceus. It is a chronic autoimmune disease often accompanied by severe weight loss.

**Pemphigus foliaceus** is the most common autoimmune disease of the horse. The majority of cases occur in mature horses, usually 5 years of age or older; a small number occur in horses 1 year of age or younger. The classic, but rarely seen, primary lesion is a vesicle or pustule. Usually, the earliest lesions visible are crusty papules best seen in lightly or non-haired skin adjacent to mucocutaneous junctions - the nostrils, eyelids or lips. Lesions rapidly coalesce to form multifocal or diffuse areas of crusting. It occurs as a generalized scabby, weeping dermatitis but it may be localized as circumscribed, circular lesions in the mouth and vulva and on the skin at circumscribed junctions. The lesions are subepidermal bullae from which the top layer can be pulled away, and are sore to the touch. In some cases the lesions are around the coronary bands on all limbs. Edema of the extremities, especially the hindlimbs, and the ventral abdominal region are commonly present.

The differential diagnoses include all skin diseases caused by scaling and crusting. These include dermatophilosis, dermatophytosis, systemic granulomatous disease and primary or idiopathic abnormalities of keratinization.

A direct immunofluorescence examination, consisting of a fluorescein–antihorse IgG applied to the lesion, can confirm the diagnosis. Corticosteroid or gold (aurothioglucose) therapy has been reported to effect improvement but an
inexorable deterioration is usual. Pemphigus foliaceus is recorded in goats as a widespread disease characterized by the presence of scales, sometimes in heavy crusts, and involvement of the coronets.

**CLINICAL PATHOLOGY**
Examination of skin scrapings or swabs for parasitic, bacterial or other agents is essential. Culture and sensitivity tests for bacteria are advisable to enable the best treatment to be selected. Skin biopsy may be of value in determining the causal agent. In allergic or parasitic states there is usually an accumulation of eosinophils in the inflamed area. In mycotic dermatitis organisms are usually detectable in the deep skin layers although they may not be cultivable from superficial specimens.

**DIAGNOSIS**
The clinical features of dermatitis are apparent. The characteristic features of the etiological types of dermatitis are described under each specific disease. Diagnostic confirmation is by histopathological demonstration in a biopsy specimen.

**DIFFERENTIAL DIAGNOSIS**
- **Hyperhidrosis and anhidrosis** are dysfunctions of sweating and have no cutaneous lesion
- **Cutaneous neoplasm** is differentiable on histopathological examination
- **Epitheligenesis imperfecta** is a congenital absence of all layers of skin
- **Vascular nevus** is a congenital lesion commonly referred to as 'birth mark'

**TREATMENT**
Primary treatment must be to remove the noxious physical or chemical agent from the environment or to supplement the diet to repair a nutritional deficiency. The choice of a suitable treatment for infected skin diseases will depend upon the accurate identification of the etiological agent.

**Supportive treatment** includes both local and systemic therapy. Local applications may need to be astringent either as powders or lotions in the weeping stage or as greasy salves in the scabby stage. The inclusion of corticosteroids or antibacterial preparations is recommended in allergic states and it is desirable to prescribe sedative or anesthetic agents when pain or itching is severe.

If shock is present, parenteral fluids should be administered. If the lesions are extensive or secondary bacterial invasion is likely to occur, parenterally administered antibiotics or antifungal agents may be preferred to topical applications. To facilitate skin repair, a high protein diet or the administration of protein hydrolysates or amino acid combinations may find a place in the treatment of valuable animals. Non-specific remedies such as gold-containing remedies (e.g. aurothioglucose) are commonly used in autoimmune diseases such as pemphigus.

The use of vaccines as prophylaxis in viral and bacterial dermatitides must not be neglected. Autogenous vaccines may be most satisfactory in bacterial infections. An autogenous vaccine is particularly recommended in the treatment of staphylococcal dermatitis in horses and bovine udder impetigo in which long and repeated courses of treatment with penicillin produce only temporary remission. An autogenous vaccine produces a cure in many cases.

**REFERENCES**

**PHOTOSENSITIZATION**

**ETIOLOGY AND EPIDEMIOLOGY**
If photosensitizing substances (photodynamic agents) are present in sufficient concentration in the skin, dermatitis occurs when the skin is exposed to light. Photodynamic agents are substances that are activated by light and may be ingested preformed (and cause primary photosensitivity) or be products of abnormal metabolism (and cause photosensitization due to aberrant synthesis of pigment) or be normal metabolic products that accumulate in tissues because of faulty excretion through the liver (and cause hepatoportogenous photosensitization). Faulty excretion through the liver may be due to hepatitis, caused in most instances by poisonous plants, or to biliary obstruction caused by crystal-associated cholangio-hepatopathy, or rarely by cholangio-hepatitis or biliary calculi.

**Primary photosensitization** Photosensitization due to the ingestion of exogenous photodynamic agents usually occurs when the plant is in the lush green stage and is growing rapidly. Livestock are affected within 4–5 days of going on to pasture and new cases cease soon after the animals are removed. In most cases the plant responsible must be eaten in large amounts and will therefore usually be found to be a dominant inhabitant of the pasture. All species of animals are affected by photodynamic agents, although susceptibility may vary between species and between animals of the same species. Photosensitizing substances that occur naturally in plants include:
- Dianthrone derivatives – hyperin in *Hypericum perforatum* (St John's wort) and other *Hypericum* spp. and
- Fagopyrin in seeds and dried plants of *Fagopyrum esculentum* (buckwheat)
The photosensitizing substance is in all photosensitization due to aberrant pigment synthesis

The only known example in domestic animals is inherited congenital porphyria, in which there is an excessive production in the body of porphyrins, which are photosensitizing.

Hepatogenous photosensitization

The photosensitizing substance is in all instances phylloerythrin, a normal end-product of chlorophyll metabolism excreted in the bile. When biliary secretion is obstructed by hepatitis or biliary duct obstruction, phylloerythrin accumulates in the body and may reach levels in the body of porphyrins, which are photosensitizing in sheep.

Miscellaneous chemicals including phenothiazine (its metabolic end-product phenothiazine sulfoxide is photosensitizing to calves), rose Bengal and acridine dyes

Cows treated with corticosteroids to induce calving may develop a photosensitive dermatitis of the teats, escutcheon and udder. Its occurrence is sporadic and does not appear to be related to a particular drug.

General signs

These become intense irritation and the animal rubs the affected parts, often lacerating the face by rubbing it in bushes. When the teats are affected the cow may kick at them and walk into ponds to immerse the teats in water, sometimes rocking backwards and forwards as if to cool the affected parts. In nursing ewes there may be resentment towards the lambs sucking, and heavy lamb mortalities due to starvation may result.

Local edema is often severe and may cause drooping of the ears, closure of the eyelids and nostrils, causing dyspnea, and dysphagia due to swelling of the lips. An early sign is increased lacrimation, with the initially watery discharge developing into a thicker, serous discharge accompanied by blepharospasm and swelling of the eyelids. Initial erythema of the muzzle is followed by fissuring, then sloughing of the thick skin. Sensitization is primary or due to hepatic insufficiency:

- Feeding on rapeseed or canola (Brassica rapa), kale, lucerne or alfalfa (Medicago sativa), burr medic or burr trefoil (Medicago minima, Trifolium hybridum (alsike or Swedish clover), Erodium cicutarium and Erodium moschatum (lamb’s tongue, plantain).
- Cattle feeding on water-damaged or moldy alfalfa hay or alfalfa silage; extensive outbreaks usually with no signs suggestive of hepatic disease.
- Cattle, sheep and horses grazing lush pasture; many clinical cases occur sporadically.
- Corticosteroids used systemically to terminate parturition in cows.
- Phenanthridium used in the treatment of trypanosomiasis.

PATHOGENESIS

Penetration of light rays to sensitized tissues causes local cell death and tissue edema. Irritation is intense because of the edema of the lower skin level, and loss of skin by necrosis or gangrene and sloughing is common in the terminal stages. Nervous signs may occur and are caused either by the photodynamic agent, as in buckwheat poisoning, or by liver dysfunction.

Hepatogenous photosensitization involves production of a toxin, by a higher plant, fungus or cyanobacterium (algae), that causes liver damage or dysfunction, resulting in the retention of the photosensitizing agent phylloerythrin.

CLINICAL FINDINGS

General signs

These commence with intense irritation and the animal rubs the affected parts, often lacerating the face by rubbing it in bushes. When the teats are affected the cow may kick at them and walk into ponds to immerse the teats in water, sometimes rocking backwards and forwards as if to cool the affected parts. In nursing ewes there may be resentment towards the lambs sucking, and heavy lamb mortalities due to starvation may result.

Local edema is often severe and may cause drooping of the ears, closure of the eyelids and nostrils, causing dyspnea, and dysphagia due to swelling of the lips. An early sign is increased lacrimation, with the initially watery discharge developing into a thicker, serous discharge accompanied by blepharospasm and swelling of the eyelids. Initial erythema of the muzzle is followed by fissuring, then sloughing of the thick skin. Sensitization is primary or due to hepatic insufficiency:

- Feeding on rapeseed or canola (Brassica rapa), kale, lucerne or alfalfa (Medicago sativa), burr medic or burr trefoil (Medicago minima, Trifolium hybridum (alsike or Swedish clover), Erodium cicutarium and Erodium moschatum (lamb’s tongue, plantain).
- Cattle feeding on water-damaged or moldy alfalfa hay or alfalfa silage; extensive outbreaks usually with no signs suggestive of hepatic disease.
- Cattle, sheep and horses grazing lush pasture; many clinical cases occur sporadically.
- Corticosteroids used systemically to terminate parturition in cows.
- Phenanthridium used in the treatment of trypanosomiasis.
hair and finally gangrene. They have a characteristic distribution, restricted to the unpigmented areas of the skin and to those parts which are exposed to solar rays. They are most pronounced on the dorsum of the body, diminishing in degree down the sides and are absent from the ventral surface. The demarcation between lesions and normal skin is very clear-cut, particularly in animals with broken-colored coats.

Predilection sites for lesions are the ears, conjunctiva, causing opacity of the lateral aspect of the cornea, eyelids, muzzle, face, the lateral aspects of the teats and, to a lesser extent, the vulva and perineum. In solid black cattle dermatitis will be seen at the lips of the vulva and on the edges of the eyelids, and on the cornea. Linear erosions often occur on the tip and sides of the tongue in animals with unpigmented oral mucosa. In severe cases the exudation and matting of the hair and local edema causes closure of the eyelids and nostrils. In the late stages necrosis or dry gangrene of affected areas leads to sloughing of large areas of skin.

Systemic signs
These include shock in the early stages, due to extensive tissue damage. There is an increase in the pulse rate with ataxia and weakness. Subsequently a considerable elevation of temperature (41–42°C, 106–107°F) may occur.

Nervous signs
These including ataxia, posterior paralysis and blindness; depression or excitement are often observed. A peculiar sensitivity to water is sometimes seen in sheep with facial eczema: when driven through water they may lie down in it and have a convulsion.

Liver insufficiency
Signs are described elsewhere and may accompany photosensitive dermatitis when it is secondary to liver damage.

CLINICAL PATHOLOGY
There are no suitable field tests to determine whether or not photosensitivity is present.

Hepatogenous photosensitization can be diagnosed by analysis of plasma phylloerythrin concentration using a spectroscopic method. Plasma or serum fluorescence can be used to measure the elevation of phylloerythrin above normal levels prior to hepatogenous photosensitization.8 The levels of phylloerythrin in plasma of lambs grazing Narthecium ossifragum are increased from a normal of less than 0.1 μmol/L to 0.3 μmol/L when clinical signs are evident.8 The concentration of phylloerythrin in the skin began increasing 2–3 days later than that in the blood.

NECROPSY FINDINGS
In primary photosensitization, lesions are restricted to white-haired or pale-skinned areas of skin or mucosa that have been exposed to sunlight, and vary from necrosis to gangrene. Lesions characteristic of hepatic injury or metabolic defects of porphyrin metabolism are described elsewhere.

Diffuse hepatocellular hydropic degeneration and hyperplasia of the smooth endoplasmic reticulum associated with marked multifocal cholangitis in the portal triads with bile duct proliferation are characteristic of the hepatic lesions of sheep grazing Bracharia decumbens.9 Foam cells are present in the liver and mesenteric and hepatic lymph nodes of cattle grazing Bracharia spp.10 Hepatocellular degeneration is the primary event in alveol photosensitization in sheep.6 High concentrations of conjugated episapogenins are present in both liver and bile in alveol-affected lambs.

DIFFERENTIAL DIAGNOSIS
The diagnosis of photosensitivity depends almost entirely on the distribution of the lesions. It can be readily confused with other dermatitides if this restriction to unpigmented and hairless parts is not kept in mind.

- Myotic dermatitis is often mistaken for photosensitization because of its tendency to commence along the back line and over the rump, but it occurs on colored and white parts alike
- Frequent wetting, as in periods of heavy rainfall, along the back in horses or cattle with a dense hair coat
- Bighead of rams associated with Clostridium novyi infection may also be confused with photosensitization but the local swelling is an acute inflammatory edema and many clostridia are present in the lesion
- The eye lesions in photosensitization have been confused with those of pink-eye but that disease is not accompanied by extensive dermatitis.

Treatment
Primary treatment includes immediate removal from direct sunlight, prevention of ingestion of further toxic material and the administration of laxatives to eliminate toxic materials already eaten. In areas where the disease is enzootic the use of dark-skinned breeds may make it possible to utilize pastures that would otherwise be too dangerous.

Local treatment will be governed by the stage of the lesions. Nonsteroidal anti-inflammatory drugs (NSAIDs), corticosteroids or antihistamines can be administered parenterally and adequate doses maintained. To avoid septicemia the prophylactic administration of antibiotics may be worthwhile in some instances.

Diseases of the hair, wool, follicles, skin glands, horns, and hooves

ALOPECIA AND HYPOTRICHOSIS

ETIOLOGY
Alopecia is complete absence of the hair or wool coat; hypotrichosis is less than the normal amount of hair or wool. Both may be caused by the following conditions.

Failure of follicles to develop
- Congenital hypotrichosis.

Loss of follicles
- Cicatricial alopecia due to scarring after deep skin wounds that destroy follicles. Cicatricial alopecia occurs following permanent destruction of the hair follicles, and regrowth of hair will not occur. Examples include physical, chemical or thermal injury, severe furunculosis, neoplasia and certain infections such as cutaneous onchocerciasis.

Failure of the follicle to produce a fiber
- Inherited symmetrical alopecia
- Congenital hypotrichosis
- Hair-coat-color-linked follicle dysplasia
- Inherited dysequoiosis and dyskeratosis
- In baldy calves and adenohypophyseal hypoplasia
Congenital hypothyroidism (goiter) due to iodine deficiency in the dam
- After viral infection of the dam, alopecia congenitally in the newborn, e.g. after bovine virus diarrhea in cattle and infection by a similar virus in sheep (Border disease)
- Neurogenic alopecia due to peripheral nerve damage
- Infection in the follicle
- Alopecia areata of horses and, less commonly, cows characterized by one or more round lesions of spontaneously disappearing, nonscarring alopecia over the face, neck, shoulders and brisket. At histopathological examination normal skin contains accumulations of lymphocytes around the hair follicles.

Loss of preformed fibers
- Dermatomyoses — ringworm
- Mycotic dermatitis in all species due to *D. rogselae*
- Metabolic alopecia subsequent to a period of malnutrition or severe illness — a break in the wool, e.g. excessive whale, palm or soya oil in milk replacer to calves; the fibers grown during the period of nutritional or metabolic stress have a zone of weakness and are easily broken
- Traumatic alopecia due to excessive scratching or rubbing associated with louse, tick or itch-mite infestations; rubbing against narrow doors, feed troughs or tethers in confined housing, against harness in working animals
- Poisoning by thallium, selenium, arsenic, mercury or the tree *Leucaena leucocephala*
- Idiopathic hair loss from the tail-swatch of well-fed beef bulls
- In sterile eosinophilic folliculitis of cattle
- Wool slip
- In many primary skin diseases, e.g. parakeratosis, hyperkeratosis, dermatis, cutaneous neoplasia, sarcoid, pythiosis hair is lost at the site of local lesions.

**PATHOGENESIS**
Normal shedding of hair fibers is a constant but largely unexplained process, especially during significant changes in environmental temperature. The long winter coat is shed in response to warmer spring temperatures and increased hours of sunlight, and rapidly regrows as environmental temperatures fall in the autumn. In inherited hair defects there may be a reduction in follicle numbers or a reduced capacity of each follicle to produce fibers. Chemical depletion produced by cytotoxic agents, such as cyclophosphamide, occurs as a result of induced cytoplasmic degeneration in some of the germinative cells of the bulb of the wool follicle. The alteration in cell function is temporary, so that regrowth of the fiber should follow.

**CLINICAL FINDINGS**
When alopecia is due to breakage of the fiber, the stumps of old fibers or developing new ones may be seen. When fibers fail to grow the skin is shiny and in most cases is thinner than normal. In cases of congenital follicular aplasia, the ordinary covering hairs are absent but the coarser tactile hairs around the eyes, lips and extremities are often present. Absence of the hair coat makes the animal more susceptible to sudden changes of environmental temperature. There may be manifestations of a primary disease and evidence of scratching or rubbing.

Congenital hypotrichosis results in alopecia which is apparent at birth or develops within the neonatal period.

**CLINICAL PATHOLOGY**
If the cause of the alopecia is not apparent after the examination of skin scrapings or swabs, a skin biopsy will reveal the status of the follicular epithelium.

**DIFFERENTIAL DIAGNOSIS**
Diagnostic confirmation of alopecia is by visual recognition, the diagnostic problem being to determine the primary cause of the hair or fiber loss.

- **Hypotrichosis** is a reduction in numbers of fibers instead of a complete absence.
- Inherited diseases of the skin are presented in Chapter 34.

**TREATMENT**
Primary treatment consists of removing the causes of trauma or other damage to fibers. In cases of faulty follicle or fiber development treatment is not usually attempted.

**REFERENCES**

**ACHROMOTRICHIA**
Deficient pigmentation in hair or wool fiber as follows:

- Bands of depigmentation in an otherwise black wool fleece are the result of a transitory deficiency of copper in the diet
- Cattle on diets containing excess molybdenum and deficient copper show a peculiar speckling of the coat caused by an absence of pigment in a proportion of hair fibers. The speckling is often most marked around the eyes, giving the animal the appearance of wearing spectacles
- General loss of density of pigmentation in all coat colors, e.g. Hereford cattle shade off from their normal deep red to a washed-out orange.

**LEUKODERMA AND LEUKOTRICHIA**
Several skin diseases of the horse are characterized by an acquired loss of melanin pigment in the epidermis of hair. Melanocytes in the epidermis and those in the hair bulbs are frequently affected independently. Leukotrichia occurs when the melanocytes in the hair bulbs lose their normal amount of melanin pigment. When the melanocytes in the epidermis are affected and the skin loses normal pigmentation, the abnormality is leukoderma. The etiology and pathogenesis of leukoderma are unknown. Reticulated leukotrichia, spotted leukotrichia and juvenile Arabian leukoderma have been described.

**VITILIGO**
Patchy depigmentation of the skin with premature graying of the local hair is not uncommon in cattle and horses. The usual manifestation is the appearance of patches of gray or white hair — 'snowflakes' — in an otherwise pigmented coat. The defect is esthetic only. Histopathological examination reveals a complete absence of melanocytes from affected areas but the cause is unknown in most cases. A genetic etiology is suspected in Arabian horses and Holstein–Friesian cattle. It can also be caused by:

- Application of 'supercooled' instruments that selectively destroy melanocytes, the basis for freeze branding
- Prolonged pressure, e.g. by poorly fitting harness
- X-irradiation
- An idiopathic state in horses, usually during a debilitating disease, with patchy depigmentation of skin appearing on the prepuce, perineum, underneath the tail, and on the face. There is no discontinuity of the skin.

**SEBORRHEA**
**ETIOLOGY**
Seborrhea is an excessive secretion of sebum on to the skin surface. In large animals it is always secondary to dermatitis or other skin irritation, e.g.:

- Exudative dermatitis of pigs associated with *S. hyicus*
CLINICAL PATHOLOGY
The primary cause of the seborrhea may be diagnosed by a suitable examination for the presence of parasitic or bacterial pathogens.

DISEASES OF THE HAIR, WOOL, SKIN GLANDS, HORNS AND HOOVES

Greasy heel of horses, including infection with S. hyicus
Greasy heel of cattle
Flexural seborrhea of cattle.

PATHOGENESIS
Increased blood supply to the skin and increased hair growth appear to stimulate the production of sebum, but why seborrhea is provoked in some individuals and not in others is unknown.

CLINICAL FINDINGS
In primary seborrhea there are no lesions, only excessive greasiness of the skin. The sebum may be spread over the body surface like a film of oil or be dried into crusts, which can be removed easily. Sebaceous glands may be hypertrophied.

Flexural seborrhea
Flexural seborrhea is most common in young, periparturient dairy cows. Severe inflammation and a profuse outpouring of sebum appear in the groin between the udder and the medial surface of the thigh, or in the median fissure between the two halves of the udder. Extensive skin necrosis follows, causing a pronounced odor of decay, which may be the first sign observed by the owner. Irritation may cause lameness and the cow may attempt to lick the part. Shedding of the oily, malodorous skin leaves a raw surface beneath; healing follows in 3–4 weeks.

Greasy heel of cows
Cows grazing constantly irritated, wet pastures, or in very muddy conditions in tropical areas may develop local swelling, with deep fissuring of the skin and an outpouring of evil-smelling exudate, on the back of the pastern of all four feet but most severely in the hind limbs. Affected animals are badly lame and their milk yield declines sharply. Removing the cows to dry land and treating systemically with a broad-spectrum antibiotic effects a rapid recovery.

Greasy heel of horses (scratches)
Greasy heel occurs mostly on the hind pastern of horses that stand continuously in wet, insanitary stables. Some cases do occur in well managed stables. It has been suggested that secondary infections associated with either S. aureus and D. congolensis may be causative factors. Dermatophytosis, chorionic mange and photosensitization are also possible causative factors.

Lameness and soreness to touch are due to excoriation called 'scratches' on the back of the pastern that extend down to the coronary band. The skin is thick and greasy and, if neglected, the condition spreads around to the front and up the back of the leg; this involvement can be severe enough to interfere with normal movement of the limb.

TREATMENT
The skin must be kept clean and dry. Affected areas should be defatted with hot soap and water washes, then properly dried, and an astringent lotion, e.g. white, lotion, should be applied daily. In acute cases of greasy heel the application at 3-5 day intervals of an ointment made up of five parts salicylic acid, three parts boric acid, two parts phenol, two parts mineral oil and two parts petroleum jelly is recommended. Long-standing cases profit from the twice-daily washing of the part and covering with an ointment containing an antibiotic, a fungistat and a corticosteroid, e.g. gentamicin, clotrimazole, betamethasone.

FOLLICULITIS

ETIOLOGY
Infection and inflammation of hair follicles associated with suppurative organisms, including staphylococci. Identifiable forms of folliculitis as individual diseases include:
- Staphylococcal dermatitis of horses
- Contiguous acne of horses
- Benign facial folliculitis of sucking lambs
- Demodectic mange
- Bovine sterile eosinophilic folliculitis.

PATHOGENESIS
Sebaceous gland ducts blocked by inspissated secretion and epithelial debris or by pressure become infected. Folliculitis is also a sequel to seborrhea, with hypertrophy of sebaceous glands and dilatation of their ducts.

CLINICAL FINDINGS
The sequence of lesion development is:
- Nodules around the base of the hair, then pustules, then crusts, finally hair fiber loss.
- Itching may occur, but pain and rupture of pustules under pressure are more common. Pustule rupture leads to contamination of the surrounding skin and development of further lesions.

In bovine sterile, eosinophilic folliculitis, the multiple lesions are crusted, alopecic, 3–5 cm diameter nodules on all parts of the body except the limbs. They are composed largely of eosinophils and are negative on culture.

CLINICAL PATHOLOGY
Swabs should be taken for bacteriological and parasitological examination.

DIFFERENTIAL DIAGNOSIS
Diagnostic confirmation is by demonstration of infection of hair follicles in a biopsy specimen.

- Udder impetigo of cattle: lesions are superficial and confined to the udder
- Infectious dermatitis (contagious pyoderm) of baby pigs associated with streptococci and staphylococci; lesions are limited to face and caused by bites from needle teeth
- Exudative epidermitis of face in adult sheep
- Leg dermatitis down to coronet of sheep
- Chronic pectoral and ventral midline abscesses in horses due to Corynebacterium pseudotuberculosis; not a skin lesion but it resembles furunculosis.

TREATMENT
Primary treatment commences with cleaning the skin by washing followed by a disinfectant rinse. Affected areas should be treated with antibacterial ointments or lotions. If the lesions are extensive the parenteral administration of antibiotics is recommended. The course of treatment should last 1 week; in chronic cases this may need to be at least 1 month; a broad-spectrum preparation such as trimethoprim–sulfadiazine is recommended. In stubborn cases an autogenous vaccine may be helpful.

Supportive treatment – infected animals should be isolated and grooming tools and blankets disinfected.

DISEASES OF HOOVES AND HORNS
Diseases of the hooves are presented in textbooks on large animal surgery and lameness in horses and cattle.

Horn cancer is covered in the section on squamous-cell carcinoma of the skin,
and hoof diseases that cause lameness are listed in Table 13.1.

**Skin diseases of the bovine digit associated with lameness**

Diseases of the skin of bovine digit include digital dermatitis (hairy heel warts), interdigital necrobacillosis (foot rot), dermatitis verrucosa and interdigital hyperplasia. These are presented in Chapters 16–20.

**Sloughing of the hooves and dewclaws (chestnuts)**

Separation of the hooves from the sensitive laminae and, in severe cases, sloughing of the horn occur in:

- Severe edema of the legs, due to limb lymphangitis or from severe trauma, causing capillary dilatation and fluid effusion into the laminar tissues
- Burns in grass fires where only the undersurface of the body is burned
- Coronitis occurring as part of pemphigus in horses
- Horses poisoned by eating mushrooms
- Terminally in laminitis.

There is no treatment once the hooves have sloughed and all attempts should be made to avoid it if separation is already evident at the coronet. Reduction of the swelling in the limb is critical, requiring enhancement of lymphatic and vascular drainage from the area.

**REVIEW LITERATURE**

**REFERENCE**

**Diseases of the subcutis**

**SUBCUTANEOUS EDEMA (ANASARCA)**

**ETIOLOGY**

Extensive accumulation of edema fluid in the subcutaneous tissue is part of general edema and caused by the same diseases, as follows.

**Increased hydrostatic pressure**

- Congestive heart failure
- Vascular compression by tumor, e.g. anterior mediastinal lymphosarcoma, udder engorgement in heifer about to calve.

**Hypoproteinemic edema**

- In liver damage with reduced albumin production due to liver insufficiency, especially fascioliasis
- Renal damage with protein loss into urine occurs rarely in animals.

**DIFFERENTIAL DIAGNOSIS**

Diagnostic confirmation is by clinical detection of serous fluid in a subcutaneous site.

- In cattle, extravasation of urine as a result of urethral obstruction and perforation
- Subcutaneous hemorrhage, hematoma or seroma, which is not necessarily dependent, nor bilaterally symmetrical
- Ventral hernia, usually unilateral and does not pit on pressure
- Cellulitis, usually asymmetric, hot, often painful, does not pit on pressure and can be sampled by needle puncture

**RENAL AMYLOIDOSIS**

- Protein-losing enteropathy, e.g. in intestinal lymphosarcoma
- Intestinal nematodiasis
- Protein starvation

**Vascular damage**

- In purpura hemorrhagica
- Anasarca in hypovitaminosis A
- Subcutaneous plaques of equine infectious anemia and dourine
- Subcutaneous plaques in dourine
- Horses standing in black walnut shavings as bedding

**Inflammatory edema**

Many bacteria cause local edema due to infection:

- Clostridium spp are the most noted
- Anthrax in swine and horses
- Sporadic lymphangitis of horses
- Insect, especially bee, stings

**Fetal anasarca**

Sporadic cases due to unknown causes are sometimes associated with deformities, e.g. in Awassi sheep

**ANGIOEDEMA (ANGIONEUROTIC EDEMA)**

**ETIOLOGY**

Transient, localized subcutaneous edema due to an allergic reaction and caused by endogenous and exogenous allergens provokes either local or diffuse lesions. Angioedema occurs most frequently in cattle and horses on pasture, especially during the period when the pasture is in flower. This suggests that the allergen is a plant protein. Fish meal may also provoke an attack. Recurrence in individual animals is common.

**PATHOGENESIS**

After an initial erythema, local vascular dilatation is followed by leakage of plasma through damaged vessels.

**CLINICAL FINDINGS**

Local lesions most commonly affect the head and diffuse edema of the muzzle, eyelids, conjunctiva and cheeks. Occasionally only the conjunctiva is affected, so that the eyelids are puffy, the nicitating membrane swollen and protruding, and laceration is profuse. Affected parts are not painful to touch but shaking the head and rubbing against objects suggest irritation. Salivation and nasal discharge may be accompanying signs.

**Perineal involvement** includes vulvar swelling, often asymmetrical, and the perianal skin, and sometimes the skin of the udder, is swollen and edematous. When the udder is affected, the teats and base of the udder are edematous and cows may paddle with the hind limbs, suggesting irritation in the teats. Edema of the thorax may lead to anasarca, or hypotension and collapse.

**REFERENCE**

of the lower limbs, usually from the knees or hocks down to the coronets, is a rare sign.

Systemic signs are absent, except in those rare cases where angioedema is part of a wider allergic response, when, for example, a lung is punctured, or in cases of severe interstitial pulmonary edema, air escapes under the visceral pleura and passes to the hilus of the lung, hence to beneath the parietal pleura, between the muscles and into the subcutis.

CLINICAL PATHOLOGY
The blood eosinophil count is often within the normal range, but may be elevated from a normal level of 4–5% up to 12–15%.

DIFFERENTIAL DIAGNOSIS
Diagnostic confirmation is found with sudden onset and disappearance of edema at the typical sites.

- Subcutaneous edema (above) due to vascular pressure occurs mostly in dependent parts and is not irritating
- In horses, and rarely in cattle, angioedema may be simulated by purpura hemorrhagica, but hemorrhages are usually visible in the mucosae in purpura.

TREATMENT
Primary treatment to remove the specific cause is usually impossible but affected animals should be removed from the suspected source of allergens. Cattle running at pasture should be confined and fed on dry feed for at least a week.

Supportive treatment to relieve the vascular lesion is always administered even though spontaneous recovery is the rule. In acute cases with severe dyspnea epinephrine can be administered parenterally, but cautious intravenous injection is recommended. For subacute cases corticosteroids or other anti-inflammatories are preferred over antihistamines or epinephrine; usually only one injection is required.

SUBCUTANEOUS EMPYSEMA
ETIOLOGY
Empysema, free gas in the subcutaneous tissue, occurs when air or gas accumulates in the subcutaneous tissue as a result of:
- Air entering through a cutaneous wound made surgically or accidentally
- Air entering tissues through a discontinuity in the respiratory tract lining, e.g. in fracture of nasal bones; trauma to pharyngeal, laryngeal, tracheal mucosa caused by external or internal trauma as in lung puncture by a fractured rib; a foreign body, as in traumatic reticulitis
- Rumen gases migrating from a rumenotomy or ruminal trocharization
- Extension from a pulmonary emphysema
- Gas gangrene infection.

PATHOGENESIS
Air moves very quickly through fascial planes, especially when there is local muscular movement. For example when a lung is punctured, or in cases of severe interstitial pulmonary edema, air escapes under the visceral pleura and passes to the hilus of the lung, hence to beneath the parietal pleura, between the muscles and into the subcutis.

CLINICAL FINDINGS
Visible subcutaneous swellings are soft, painless, fluctuating and grossly crepitant to the touch, but there is no external skin lesion. In gas gangrene, discoloration, coldness and oozing of serum may be evident. Empysema may be sufficiently severe and widespread to cause stiffness of the gait and interference with feeding and respiration.

CLINICAL PATHOLOGY
None is necessary except in cases of gas gangrene, when a bacteriological examination of fluid from the swelling should be carried out to identify the organism present.

DIFFERENTIAL DIAGNOSIS
Diagnostic confirmation is based on the observation of crepitus and the extreme mobility of the swelling; these distinguish emphysema from other superficial swellings.

- Anasarca, dependent and pits on pressure (see above)
- Hematoma, seroma at injury sites, confirmed by needle puncture (see below)
- Cellulitis is accompanied by toxemia, confirmed by needle puncture.

TREATMENT
Primary treatment is to close the entry point for the gas but this is usually impossible to locate or to close. Supportive treatment is only necessary when the emphysema is extensive and incapacitating; when multiple skin incisions may be required. Gas gangrene requires immediate and drastic treatment with antibiotics.

LYMPHANGITIS
This is characterized by inflammation and enlargement of the lymph vessels and is usually associated with lymphadenitis.

ETIOLOGY
Lymphangitis is due in most cases to local skin infection with subsequent spread to the lymphatic system. Common causes are as follows.

- Glanders, epizootic lymphangitis, sporadic lymphangitis, ulcerative lymphangitis due to C. pseudotuberculosis
- Strangles in cases where bizarre location sites occur
- In foals ulcerative lymphangitis associated with Streptococcus zooepidemicus.

CATTLE
- Skin farcy associated with Nocardia farcinica, Rhodococcus equi
- Cutaneous tuberculosis associated with atypical mycobacteria, rarely Mycobacterium bovis.

PATHOGENESIS
Spread of infection along the lymphatic vessels causes chronic inflammation and thickening of the vessel walls. Abscesses often develop, with discharge to the skin surface through sinuses.

CLINICAL FINDINGS
An indolent ulcer usually exists at the original site of infection. The lymph vessels leaving this ulcer are enlarged, thickened and tortuous and often have secondary ulcers or sinuses along their course. Local edema may result from lymphatic obstruction. In chronic cases much fibrous tissue may be laid down in the subcutis and chronic thickening of the skin may follow. The medial surface of the hindlimb is the most frequent site, particularly in horses.

CLINICAL PATHOLOGY
Bacteriological examination of discharges for the presence of the specific bacteria or fungi is common practice.

TREATMENT
Primary treatment requires vigorous, early surgical excision or specific antibiotic therapy.

Supportive treatment is directed toward removal of fluid and inflammatory exudate and relief of pain.

PANNICULITIS
Panniculitis is diffuse, sterile inflammation of subcutaneous fat. Deep-seated, firm and painful nodules up to 5 cm in diameter develop, often in large numbers, anywhere over the body but especially on the neck and sides, most commonly in young horses and rarely in cattle. The lesions may fluctuate greatly in size and number, or even disappear spontaneously. In a few cases there is transient fever, reduced feed intake and weight loss. Lameness may be evident in horses with extensive lesions.

Diagnosis is by histological examination of a biopsy specimen. At necropsy examination there are no other lesions. The
lesions reduce in size and number after the administration of dexamethasone, but recur when treatment stops.  

REFERENCES

HEMORRHAGE
This is extravasation of whole blood into the subcutaneous tissues.

ETIOLOGY
Accumulation of blood in the subcutaneous tissues beyond the limit of that normally caused by trauma may be due to defects in the coagulation mechanism or to increased permeability of the vessel wall. Common causes include:
- DICumarol poisoning from moldy sweet clover hay
- Purpura hemorrhagica in horses
- Bracken poisoning in cattle, and other granulocytopenic disease. These diseases are manifested principally by petechiation and the lesions are observed only in mucosa
- Hemangiosarcoma in subcutaneous sites
- Inherited hemophilia.

PATHOGENESIS
Leakage of blood from the vascular system can cause local swellings, which interfere with normal bodily functions but are rarely sufficiently extensive to cause signs of anemia.

CLINICAL FINDINGS
Subcutaneous swellings resulting from hemorrhage are diffuse and soft with no visible effect on the skin surface. There may be no evidence of trauma. Specific locations of subcutaneous hemorrhages include the frontal aspect of the chest - due to fracture of the first rib in collisions at full gallop and often fatal through internal hemorrhage - and perivaginal at foaling, causing massive swelling of the perineum and medial aspect of the thigh.

CLINICAL PATHOLOGY
Visual examination of a needle aspirate confirms the existence of subcutaneous hemorrhage. Diagnosis of the primary cause is greatly assisted by platelet counts and prothrombin, clotting and bleeding times.

TREATMENT
Primary treatment targets removal or correction of the cause.
Supportive treatment: The hemorrhages should not be opened until clotting is completed, except in the case of a massive hemorrhage that is interfering with respiration, defecation or urination. If blood loss is severe, blood transfusions may be required. Parenteral injection of coagulants can be justified if the hemorrhages are recent and severe.

Necrosis and Gangrene
Necrosis is tissue death; gangrene is sloughing of dead tissue. When either change occurs in the skin it involves the dermis, epidermis and subcutaneous tissue.

ETIOLOGY
Severe damage to the skin in the following categories causes gangrene:
- Severe or continued trauma, e.g. pressure sores, saddle and harness galls, carpal or tarsal necrosis in recumbent animals
- Strong caustic chemicals, e.g. creosote
- Severe cold or heat, bushfires and stable fires being the worst offenders
- Frostbite is an unusual occurrence in animals unless the patient has a circulatory deficit, e.g. in the neonate, in severe shock or toxemia
- Beta-irradiation

Infections, especially:
- Erysipelas and salmonellosis in pigs
- Clostridial infections in cattle affecting subcutis and muscle
- Staphylococcal mastitis in cattle, pasteurella mastitis in sheep
- Bovine ulcerative mammillitis of the udder and teats

TREATMENT
Primary treatment requires removal of the etiological insult.
Supportive treatment comprises the application of astringent and antibacterial ointments to facilitate separation of the gangrenous tissue and to prevent bacterial infection.

SUBCUTANEOUS ABSCESSES
Most subcutaneous abscesses are matters of purely local and esthetic concern but if sufficiently extensive and active localized infections, they may cause mild toxemia. Their origins include the following:

Trauma
Most subcutaneous abscesses are the result of traumatic skin penetration with resulting infection. For example, facial subcutaneous abscesses are common in cattle eating roughage containing foxtail grass (Hordeum jubatum). Several animals in a herd may be affected at one time. The awns of these plants migrate into the...
Cheek mucosa, causing subcutaneous abscesses containing *Arcanobacterium* (formerly *Actinomyces*) *pyogenes* and *Actinobacillus* spp. The abscesses contain purulent material, are well encapsulated and must be surgically drained and treated as an open wound. Medical therapy with parenteral antimicrobials and iodine is ineffective.

**Hematogenous**

Rarely the infection reaches the site via the bloodstream, e.g. chronic pectoral abscesses of horses, infections in foals with *R. equi*, infections in all species with *Pasteurella pseudotuberculosis*, infections in lambs with *Histophilus somni* (formerly *Histophilus ovis*) or *Pseudomonas pseudomallei*.

**Extension**

Abscesses may originate by extension from lesions of furunculosis, pyoderma or impetigo, or by contagious spread by contact from an internal organ, e.g. from traumatic reticuloperitonitis.

**CUTANEOUS CYSTS**

Cysts contained by an epithelial wall enclosing amorphous contents or living tissue may be congenital, inherited defects or acquired as a result of inappropriate healing of accidental wounds. They are smooth, painless, about 1.5–2.5 cm in diameter, round and usually fluctuating, although inspissated contents may make them feel quite hard. The skin and hair coat over them is usually normal, although some may leak mucoid contents onto the skin. Epidermoid cysts are lined with skin; dermoid cysts usually contain differentiated tissue such as sebaceous glands and hair follicles; dentigerous cysts contain teeth or parts of them. Acquired cysts include apocrine, sebaceous and keratin varieties. Developmental cysts, which are present from birth, are usually located at specific anatomical sites, and include:

- **Branchial cysts** in the neck, formed from an incompletely closed branchial cleft
- **False nostril cysts** in horses
- **Wattle cysts** in goats.

Cysts may occur anywhere on the body, but most commonly they are found near the dorsal midline. In horses a common site is the base of the ear.

Other diseases that cause cutaneous nodules in horses include collagenolytic granuloma, mastocytosis, amyloidosis, lymphoma, sarcoïd and infestation with *Hypoderma* spp.

Surgical excision for cosmetic reasons is common practice.²

**REFERENCES**

**Granulomatous lesions of the skin**

Granulomatous lesions are chronic inflammatory nodules, plaques and ulcers; they are cold, hard, progress slowly and are often accompanied by lymphangitis and lymphadenitis. In many cases there is no cutaneous discontinuity, nor alopecia. Some of the common causes in animals are as follows.

**Cattle**

- *Mycobacterium* spp. especially *Mycobacterium farcinogenes*
- *Nocardia farcinica*
- *A. lignieresii*
- Infestation with *Onchocerca* sp.
- *Hypoderma* sp. larvae
- *Mucor* sp. fungi in thick-walled nodules in the skin on the posteroverentral aspect of the udder
- Lechiguana, a disease of cattle in Brazil in which very large granulomata consisting of fibrous tissue and containing *Pasteurella granulomatis* develop in subcutaneous sites in any part of the body.¹

**Sheep**

- Strawberry footrot – *D. congolesis*
- Ecthyma
- Ulcerative lesions of lower jaw and dewlap associated with *A. lignieresii*.

**Pigs**

- *Actinomyces* spp. and *B. suilfa* cause lesions on the udder.

**Horses**

- Tumorous calcinosis causes hard, painless, spherical granulomata, up to 12 cm in diameter, near joints and tendon sheaths, especially the stifle joint. Surgical removal is recommended
- Cutaneous amyloidosis
- Collagenolytic granuloma (nodular necrobiosis) – the most common nodular skin disease of the horse.⁴

The etiology is unknown. There are multiple firm nodules located in the dermis ranging in size from 0.5–5 cm in diameter. The overlying skin surface and hair are usually normal. Biopsy reveals collagenolysis. Treatment consists of surgical removal and consideration of corticosteroids Botryomycosis, or bacterial pseudomycosis, results from bacterial infection at many sites, often accompanied by a foreign body. Lesions on the limbs, brisket, ventral abdomen and scrotum vary in size from nodules to enormous fungating growths composed of firm inflammatory tissue riddled by necrotic tracts, leading to discharging sinuses, often containing small, yellow-white granules or 'grains'. Surgical excision is the only practicable solution.

Equine eosinophilic granuloma – non-alopiec, painless, nonpruritic, firm nodules, 2–10 cm in diameter and covered by normal skin develop on the neck, withers and back of horses, especially in the summer. The cause is unknown and palliative treatment, surgical excision or corticosteroid administration is usually provided.

- Systemic granulomatous disease (equine sarcoidosis)³ – a rare disease of horses characterized by skin lesions and widespread involvement of the lungs, lymph nodes, liver, gastrointestinal tract, spleen, kidney, bones, and central nervous system
- *Actinobacillus vulnali* – cutaneous faccy or glands
- *Actinomadura* spp. and *Nocardia brasiliensis* – painless mycetomas
- *Histoplasma farcinominosum* – epizootic lymphangitis
- *C. pseudotuberculosis* – ulcerative lymphangitis
- *Habronema megastoma*, *Hyphomycoses destructae* as causes of swamp cancer, bursattee, Florida horse leech and blackgran mycetoma
- Infestation with *Onchocerca* sp.
- Chronic urticaria.⁴

**REFERENCES**

**Cutaneous neoplasms**

Many cutaneous neoplasms have been recorded in large animals but at a very low incidence. A brief description of only the more common types is given here.

**PAPILLOMA AND SARCOID**

Sarcoïd of horses and cutaneous papillomatosis of horses, goats, and cattle are specific diseases. The lesions are characteristically nodular growths of viable tissue and, if there is no traumatic injury, with no discontinuity of the covering epidermis.

Aural flat warts (aural plaques) occur commonly in the horse and are
caused by the papilloma virus. Blackflies may serve as a vector. Lesions consist of one to several gray or white plaques involving the inner surface of the pinna. Similar lesions may occur around the anus, vulva and inguinal regions. The lesions are usually asymptomatic, may persist indefinitely, may regress spontaneously and are refractory to treatment.

**SQUAMOUS-CELL CARCINOMA**

This neoplasm can occur anywhere on the skin, and also in the mouth and maxillary sinus.

- **Cancer-eye** is the commonest lesion, on the eyelids and the eyeball in horses and cattle
- **Genital squamous-cell carcinomas** affecting the glans penis and prepuce of aged horses can cause fatal metastases unless amputation is performed in the early stages. Grossly similar lesions are caused by epithelial hyperplasia, habronemiosis, and squamous papillomata. Squamous-cell carcinomas also occur on the vulva of cattle and a greater incidence has been observed on unpigmented than on pigmented vulvas
- **Vulvar squamous-cell carcinoma** appears frequently in Merino ewes as a result of excessive exposure of vulvar skin to sunlight after radical perineal surgery to help control blowfly strike
- **Cancer of the horn core** in cattle and rarely in sheep is a squamous-cell carcinoma arising from the mucosa of the frontal sinus and invading the horn core; it is most prevalent in aged, white, Indian breeds of cattle. In the early stages affected animals may rub the horns against a fixed object, or shake the head frequently. A bloody discharge begins from the nostril on the affected side, or from the base of the horn, and the animal holds its head down and toward one side. The horn becomes loosened and falls off, leaving the tumor exposed to infection and fly infestation. Secondary metastases are not uncommon. The high prevalence of metastases in regional lymph nodes and internal organs discourages treatment but a phenol extract of horn core tissue is immunogenic and immunotherapy may be a successful treatment technique. Other forms of therapy are also practiced for squamous-cell carcinoma generally, including surgical excision, preferably by cryotherapy, and radiofrequency hyperthermia
- **Ear cancer** in sheep is in most cases a squamous-cell carcinoma. The lesion commences around the free edge of the ear and then invades the entire ear, which becomes a large, cauliflower-shaped mass. A high incidence may occur in some flocks but the cause is not known; the presence of papilloma virus in many aural precancerous lesions suggests that the virus may participate in the etiology

- **Ovine skin cancer**: a high incidence of epithelioamas has been recorded in some families of merino sheep in Australia. The lesions occurred on the woolled skin and were accompanied by many cutaneous cysts. It has been suggested that predisposition to the neoplasm is inherited. Metastasis is common with both epithelioamas and squamous-cell carcinomas
- **'Brand cancer'**, which occurs as a granulomatous mass at the site of a skin fire or freeze brand, is usually considered to be of chronic inflammatory rather than neoplastic origin, but squamous cell carcinomas are recorded at branding sites in sheep and cattle.
- **In goats**, the perineum is a common site for squamous-cell carcinoma. The udder, ears, and base of the horns may also be affected. Ulceration, fly strike and matting of hair are unattractive sequelae. A bilaterally symmetrical vulvar swelling due to ectopic mammary tissue that enlarges at parturition is likely to be confused with squamous-cell carcinoma. Milk can be aspirated from the swellings.

**MELANOMA**

Superficially situated melanomas occur most commonly at the tail root in aged, gray horses and rarely in dark-skinned cattle, sheep and goats. Equine lesions are not usually malignant and rarely metastasize widely. The skin is intact but ulcerates in rapidly growing tumors. Bovine melanomas are usually benign. A high rate of occurrence of malignant melanomas has been observed in neonatal pigs of the Duroc-Jersey breed. Inherited melanomas and kindred neoplasms occur commonly in Sinclair miniature and NIH miniature swine but they frequently regress spontaneously.

**NEUROFIBROMATOSIS**

This common lesion of nerves in cattle usually attracts attention only in abattoir specimens but can occur in a cutaneous form resembling a similar disease of humans, particularly high prevalence of this benign disease is recorded in breeds of European pied cattle. Clinical cases are usually recorded in calves, in which there are cutaneous lesions that appear as tumor-like lumps between the eyes and on the cheeks. They are flat, round tumors up to 8 cm in diameter and of a lumpy, elastic consistency.

**HISTIOCYTOMA**

This is a very rare benign neoplasm in farm animals but is recorded as cutaneous nodules or plaques, which bleed easily, in
goats and cattle. The lesions regress spontaneously.

**HEMANGIOMA AND HEMANGIOSARCOMA**

Benign cutaneous hemangiomas occur rarely in most species, including a rare occurrence in cattle and relatively commonly on distal parts of limbs in young horses, sometimes in neonates. The lesions are small (1–3 cm diameter), round, blue to black lumps that bleed easily and are morphologically the same as bovine cutaneous angiomata lesions. Vascular nevi in newborn foals have a very similar appearance.

Hemangiosarcomas (hemangi-epithelioma) are malignant tumors recorded relatively frequently in older horses. They are large, highly vascular, subcutaneous masses, usually associated with one or more internal lesions. The primary lesion may be internal, commonly in the spleen, or cutaneous. Recurrence after excision, extensive local infiltration and death due to anemia are common sequela.

**LIPOMA**

External lipomas are not cutaneous neoplasms but they do occur as large subcutaneous masses and invade fascia and muscle. They are generally susceptible to surgical removal.

**HEMATOSARCOMA**

Inherited congenital lethgo is a rare disorder characterized by cutaneous infiltrates of blood cells. Only inflammatory changes occur in lipomas, while hematoma is characterized by the presence of a tumor-like nodule composed of overgrowth of mature cells, which normally occur in the affected part but often with one element predominating. Hematomas include hemangiosomas, ameloblastomas and rhabdomyomas. Teratomas are true neoplasms consisting of different types of tissue not native to the area in which they occur.

**CATTLE**

Cattle congenital skin neoplasms described include mast cell tumors, lymphosarcoma, myxoma and vascular hamartoma.

**Pigs**

The literature on congenital and hereditary tumors in pigs has been reviewed. Spindle cell sarcoma, malignant melanoma and papillomatosis are common congenital tumors of the skin of pigs. Congenital cutaneous papillomatosis of the head and neck of a newborn piglet has been described from a pig-breeding farm where sporadic cutaneous papillomatosis of the prepuce and scrotum had previously occurred in several boars.

**Foals**

Congenital tumors in foals are rare. Congenital skin tumors are of the papillomatous, vascular and melanocytic types. The vascular tumors are capillary hemangiomias, cavernous hemangiomias, and hemangiosarcomas.

**REFERENCES**

**CONGENITAL SKIN NEOPLASMS**

Congenital tumors are defined as those existing at birth. A broader definition is that congenital tumors can be detected in fetuses, and newborns until 2 months of age. Embryonic tumors are those that arise during embryonic, fetal or early postnatal development from a particular organ rudiment or tissue while it is still developing. The tumors are usually present at birth but often with one element predominating. Hematoma include hemangiosomas, ameloblastomas and rhabdomyomas. Teratoma are true neoplasms consisting of different types of tissue not native to the area in which they occur.
Diseases of the conjunctiva

Some of the common diseases of the conjunctiva are listed here because they are often treated medically as they are often secondary to the presence of some other disease, and also because an examination of the conjunctiva often provides additional information on which to base a diagnosis. General practitioners need to know something of the common diseases of the eye for these reasons.

The following notes are intended only to provide guidelines to the relevant sections of Part Two, where specific forms of conjunctivitis have been described in detail.

CONJUNCTIVITIS AND KERATOCONJUNCTIVITIS

This is inflammation of the covering membrane of the eye, including the orbit and the inner surface of the eyelids. The inflammation commonly extends to layers below the conjunctiva, hence keratoconjunctivitis.

ETIOLOGY

Specific conjunctivitis

Cattle

Infectious bovine keratoconjunctivitis is associated with:

- *Moraxella bovis*, the only significant cause
- *M. bovis* with infectious bovine rhinotracheitis virus
- *Neisseria catarhalis*
- *Mycoplasma spp.*
- *Chlamydophila spp.*

Sheep

- *Rickettsia conjunctivae* is the important infection
- *N. catarhalis*
- *Mycoplasma conjunctivae*
- *Acholeplasma oculi* is also listed
- *Chlamydophila spp.*

Goats

- *R. conjunctivae*.

Pigs

- *Rickettsia spp.*

Horses

There is no well-identified specific conjunctivitis in this species but *Moraxella equi* has been recorded as a cause on several occasions.1 There is also infestation with *Thelazia spp.* and *Habronema spp.*

Specific keratitis lesions

- *Thelazia spp.* in cattle and horses
- *Onchocerca spp.* in cattle
- *Elaeophora schneideri* in sheep and goats
- *Habronema spp.* in horses
- Fungal keratopathy in foals and adult horses; *Aspergillus flavus* has been identified in some cases.

*Aspergillus fumigatus* is listed amongst the causes of mycotic keratitis in animals. Most cases begin as traumatic injuries with secondary infections or begin in eyes treated for long periods with broad-spectrum antibiotics.

Secondary diseases in which conjunctivitis is a significant but secondary part of the syndrome

Cattle

- Bovine viral diarrhea
- Bovine malignant catarrh
- Rinderpest
- Infectious bovine rhinotracheitis
- Viral pneumonia due to various viruses.

Sheep

- Blue tongue.

Pigs

- Swine influenza
- Inclusion body rhinitis.

Horses

- Equine viral arteritis
- Equine viral rhinopneumonitis.

Nonspecific conjunctivitis

- Inflammation caused by foreign bodies or chemicals, or secondarily as exposure keratitis, and conjunctivitis/herpesvirus infection in paralysis of eyelids as in listeriosis. Ant-bite conjunctivitis occurs in similar circumstances.

CLINICAL FINDINGS

Blepharospasm and weeping from the affected eye are the initial signs. Watery tears are followed by mucopurulent, then purulent ocular discharge if the lesion extends below the conjunctiva. Varying degrees of opacity of the conjunctiva may develop, depending on the severity of the inflammation. In the severest lesions there is underrunning of the conjunctiva with pus accompanied by vascularization of the cornea. During the recovery stage there is often long-lasting, diffuse opacity of the eye and terminal chronic white scar in some cases.

CLINICAL PATHOLOGY

In herd or flock outbreaks conjunctival swabs and/or scrapings should be taken for culture and examination of cells using special stains and histological techniques.

REFERENCES

Congenital defects of the eyelids and cornea

DERMOID CYSTS

Ocular dermoid cysts are solid, skin-like masses of tissue, adherent usually to the anterior surface of the eye, causing irritation and interfering with vision. The eyelid, the third eyelid and the canthus may also be involved, and the lesions may be unilateral or bilateral. When they occur at a high frequency in a population, it is likely they are inherited, as can be in Hereford cattle. It is also recorded in foals. The defect is sometimes associated with microphthalmos. Surgical ablation is recommended.

Diseases of the external ear

Ear cancer is discussed in the section on squamous cell carcinoma.

OTITIS EXTERNA

Otitis externa, inflammation of the skin and external auditory canal, can affect cattle of all ages, in isolated cases, an entire herd or in entire regions.1 The literature on the causes of otitis in cattle has been reviewed.1

Arthropod parasites, foreign bodies and sporadic miscellaneous infections may cause irritation in the ear, accompanied by rubbing of the head against objects and frequent head-shaking.

In tropical and subtropical regions, parasitic otitis is more important than in other more temperate regions.2,3 The mites *Rantanella auris* and *Dermatophagoides pteronyssinus*, the tick *Oxotus spiroerca*, larvae of the mite *Stephanopilus zahnii*, free-living nematodes (Rhabditis bovis) and the blue fly *Chrysomyia bezziana* are of importance in Europe, Africa, India and America.

*Malassezia spp.*, *Candida spp.*, *Rhodotorula mucilaginosa*, *Aspergillus spp.* and *Micelium sterilia* are common causes of otitis externa in cattle in Brazil.3,4

When the syndrome occurs in a large number of a herd, as it does in tropical countries, it is necessary to look for a specific causative agent. Rhabditis bovis is the common cause. Affected animals are depressed, eat little and appear to experience pain when they swallow, and they shake their heads frequently. Both ears are affected in most cases and there is a stinking, blood-stained discharge that creates a patch of alopecia below the ear. The area is painful when touched, the external meatus of the aural canal is...
obviously inflamed and the parotid lymph nodes are enlarged. Extension to the middle ear is an unusual sequel. Topical treatment with ivermectin and a broad-spectrum antibiotic is effective.

**OTITIS MEDIA**

Otitis media (middle ear infection) occurs in milk-fed calves from a few days of age up to 10 weeks and in weaned calves from 4–8 months and from 12–18 months of age. The major bacteria that cause otitis media in calves include *Actinomyces* spp., *C. pseudotuberculosis*, *Escherichia coli*, *Histophilus somni* (formerly *Haemophilus somnus*), *Pasteurella multocida*, *Mannheimia haemolytica*, *Pseudomonas* spp., *Streptococcus* spp. and *M. bovis*.

Introduction

Mastitis is inflammation of the parenchyma of the mammary gland regardless of the cause. Mastitis is therefore characterized by a range of physical and chemical changes in the milk and pathological changes in the glandular tissue. The most important changes in the milk include discoloration, the presence of clots and the presence of large numbers of leukocytes. There is swelling, heat, pain and edema in the mammary gland in many clinical cases. However, a large proportion of mastitic glands are not readily detectable by manual palpation nor by visual examination of the milk using a strip cup; these quarters represent subclinical infections. Because of the large numbers of subclinical cases, the diagnosis of mastitis depends largely on indirect tests, which depend, in turn, on the somatic cell concentration (SCC) or electrolyte (sodium or chloride) concentration of the milk. It seems practicable and reasonable to define mastitis as a disease characterized by the presence of a significantly increased SCC in milk from affected glands. The increased SCC is, in almost all cases, due to an increased neutrophil concentration, represents a reaction of glandular tissue to injury and is preceded by changes in the milk that are the direct result of damage to glandular tissue. However, the exact clinical and laboratory changes that occur in the udder as a result of infection can also be caused by other factors in the absence of infection. Until such time as it becomes common usage to define mastitis in terms of the sodium or chloride concentration of the milk (as measured by electrical conductivity) or increased permeability of the blood–milk barrier (as measured by albumin concentration) there appears to be no point in characterizing of mastitis because of its economic importance. Mastitis control depends on the identification of the causative agent whether it be infectious or physical.

Most of the information presented here deals almost entirely with bovine mastitis because of its economic importance, but small sections on ovine, caprine, porcine and equine mastitis are included at the end of the chapter.

Bovine mastitis

GENERAL FEATURES

A total of about 140 microbial species, subspecies and serovars have been identified as causes of bovine mastitis. These can be divided into six categories based on their relative importance in the causation of this disease:

1. Contagious pathogens:
   - Staphylococcus aureus
   - Streptococcus agalactiae
   - Mycoplasma bovis
   - Corynebacterium bovis

2. Environmental pathogens:
   - Environmental coliforms
   - Coagulase-negative staphylococci
   - Corynebacterium bovis

3. Fungal pathogens:
   - Histoplasma capsulatum
   - Candida albicans

5. Tissue opportunistic pathogens:
   - Nocardia spp.

6. Miscellaneous pathogens:
   - Actinomyces pyogenes

Etiology

- Contagious pathogens: Staphylococcus aureus, Streptococcus agalactiae, Mycoplasma bovis and Corynebacterium bovis
- Teat skin opportunistic pathogens: coagulase-negative staphylococci
- Environmental pathogens: environmental Streptococcus spp., including Streptococcus uberis and Streptococcus dysgalactiae, which are the most prevalent; less prevalent is Streptococcus equinus (formerly referred to as Streptococcus bovis).
- Environmental coliforms include the Gram-negative bacteria Escherichia coli, Klebsiella spp. and Enterobacter spp., and Arcanobacterium (formerly Actinomyces) pyogenes

CONTROL OF BOVINE MASTITIS 728
Options in the control of mastitis 729
Principles of controlling bovine mastitis 730
Mastitis control programs 730
Clinical signs
- Contagious pathogens are transmitted at time of milking; teat skin opportunistic pathogens take any opportunity to induce mastitis, environmental pathogens are from the environment and induce mastitis between milkings.
- Environmental pathogens are the most common cause of clinical mastitis in herds that have controlled contagious pathogens.
- Prevalence of infection with contagious pathogens ranges from 7–40% of cows and 6–35% of quarters.
- Prevalence of infection with environmental pathogens: coliforms 1–2% of quarters; streptococci less than 5%.

Risk factors
- Animal risk factors: prevalence of infection increases with age. Most new infections occur in dry period and in early lactation. Highest rate of clinical disease occurs in herds with low somatic cell counts (SCCs). Morphology and physical condition of teat are risk factors. Selenium and vitamin E status influence incidence of clinical mastitis.
- High-producing cows are more susceptible.
- Environmental risk factors: poor quality management of housing and bedding increases infection rate and incidence of clinical mastitis due to environmental pathogens.
- Pathogen risk factors: ability to survive in environment, virulence factors (colonizing ability, toxin production), susceptibility to antimicrobial agents.
- Economics: subclinical mastitis is a major cause of economic loss due to loss of milk production, costs of treatment and early culling.

Clinical signs
- Gross abnormalities in milk (discoloration, clots, flakes, pus).
- Physical abnormalities of udder: acute – diffuse swelling, warmth, pain, gangrene in severe cases; chronic – local fibrosis and atrophy.
- Systemic response: may be normal or mild, moderate, acute, peracute with varying degrees of anorexia, toxemia, dehydration, fever, tachycardia, ruminal stasis, and recumbency and death.

Clinical pathology
- Detection at the herd level: bulk tank milk SCCs. Culture of bulk tank milk.
- Detection at the individual cow level: abnormal looking milk, culture of composite or quarter milk samples. Indirect tests include SCCs of composite or quarter milk samples, California Mastitis Test (CMT) of quarter milk samples, inline milk conductivity tests of quarter milk samples.
- Use of selective media to differentiate Gram-positive and Gram-negative pathogens in cases of clinical mastitis.

Treatment
- Clinical mastitis in lactating cow: mild cases of clinical mastitis (abnormal secretion only) may not require treatment; however, all clinical mastitis episodes accompanied by an abnormal gland or systemic signs of illness should be treated with antimicrobial agents given by intramammary infusion (all cases) and parenterally (selected cases). Acute and peracute mastitis cases require also supportive therapy (fluid and electrolytes) and nonsteroidal anti-inflammatory agents (NSAIDs).
- Culture milk of representative clinical cases but antimicrobial susceptibility testing has not been validated.
- Dry cow therapy: intramammary infusion of long-acting antimicrobial agents at drying off provides the best treatment for subclinical mastitis due to contagious pathogens. Must adhere to milk withholding times after treatment with antimicrobial agents to prevent milk drug residues, which is major public health issue. Currently available cowside antimicrobial residue tests are not reliable.

Control
- Principle of control:
  A. Eliminate existing infections
  B. Prevent new infections
  C. Monitor udder health status
- Components of Mastitis Control Program:
  1. Use proper milking management methods
  2. Proper installation, function, and maintenance of milking equipment
  3. Dry cow management
  4. Appropriate therapy of mastitis during lactation
  5. Culling chronically infected cows
  6. Maintenance of an appropriate environment
  7. Good record keeping
  8. Monitoring udder health status
  9. Periodic review of the udder health management program
  10. Setting goals for udder health status

Environmental mastitis pathogens
- Environmental mastitis is associated with three main groups of pathogens, the coliforms (particularly E. coli and Klebsiella spp.), environmental Streptococcus spp. and Arcanobacterium pyogenes. The source of these pathogens is the environment of the cow. The major mode of transmission is from the cow to the cow by inadequate management of the environment. Examples include wet bedding, dirty lots, milking wet udders, inadequate premilking udder and teat preparation, housing systems that allow teat injuries, and poor fly control. Control strategies for environmental mastitis include a conscientious mastitis control program will eradicate Staphylococcus aureus from most dairy herds. It is much more difficult to deal with a herd that has a high prevalence of S. aureus, but S. aureus can be eradicated from low-prevalence herds.
- Mycoplasma bovis is a less common cause of contagious mastitis; it causes outbreaks of clinical mastitis that do not respond to therapy and are difficult to control. Most outbreaks of M. bovis are associated with recent introductions of new animals into the herd. Characteristically, clinical mastitis occurs in more than one quarter, there is a marked drop in milk production and there is little evidence of systemic disease. The laboratory diagnosis of mycoplasmal mastitis requires specialized media and culture conditions. Antimicrobial therapy is relatively ineffective and culling is the predominant strategy.
- Teat skin opportunistic mastitis pathogens
- The incidence of mild clinical mastitis associated with bacterial pathogens that normally reside on the teat skin is increasing, particularly in herds that have controlled major contagious mastitis pathogens. Teat skin opportunistic pathogens have the ability to create an intra-mammary infection via ascending infection through the streak canal. Accordingly, their epidemiology of infections differs from those of contagious and environmental pathogens, and it is useful to consider them in a separate category. Coagulase-negative staphylococci are the most common teat skin opportunistic mastitis pathogens.
- Environmental mastitis pathogens
- Environmental mastitis is associated with three main groups of pathogens, the coliforms (particularly E. coli and Klebsiella spp.), environmental Streptococcus spp. and Arcanobacterium pyogenes. The source of these pathogens is the environment of the cow. The major mode of transmission is from the cow to the cow by inadequate management of the environment. Examples include wet bedding, dirty lots, milking wet udders, inadequate premilking udder and teat preparation, housing systems that allow teat injuries, and poor fly control. Control strategies for environmental mastitis include a conscientious mastitis control program will eradicate Staphylococcus aureus from most dairy herds. It is much more difficult to deal with a herd that has a high prevalence of S. aureus, but S. aureus can be eradicated from low-prevalence herds.
include improved sanitation in the barn and yard areas, good premilking udder preparation so that teats are clean and dry at milking time, and fly control. Special attention is necessary during the late dry period and in early lactation.

Coliform organisms are a common cause of clinical mastitis, occasionally in a severe paraculture form. Clinical cases of coliform infection are generally found in low levels in most herds and do not routinely result in chronic infections. There is increasing evidence that, as the contagious pathogens are progressively controlled in a herd, the incidence of clinical cases associated with coliform organisms increases. The pathogenesis, epidemiology, predisposing risk factors, diagnostic problems, therapy and control methods have been the subject of extensive, worldwide research efforts.

Environmental streptococci have become a major cause of mastitis in dairy cattle. Streptococcal infections are associated with many different species, however the most prevalent species are Streptococcus uberis and Streptococcus dysgalactiae. Infections with these organisms can cause clinical mastitis that is commonly mild to moderate in nature. More frequently, these organisms cause a chronic subclinical infection with an increased milk SCC. Many herds that have implemented the five-point program for mastitis control have found that environmental streptococci represent their most common mastitis problem.

A. pyogenes is an important seasonal cause of mastitis in dry cows and late pregnant heifers in some parts of the world. Intramammary infections with A. pyogenes are severe and the gland is almost always lost to milk production. Several other pathogens are included in the environmental class of infections. These pathogens invade the mammary gland when defense mechanisms are compromised or when they are inadvertently delivered into the gland at the time of intramammary therapy. This group of opportunistic organisms includes Pseudomonas spp., yeast agents, Prototexa spp., Serratia marcescens and Nocardia spp. Each of these agents has unique microbiological culture characteristics, mechanisms of pathogenesis and clinical outcomes. These infections usually occur sporadically. However, outbreaks can occur in herds or in an entire region and are usually the result of problems with specific management of hygiene or therapy. For example, mastitis associated with Pseudomonas aeruginosa has occurred in outbreaks associated with contaminated wash hoses in milking parlors. Iodide germicides used in wash lines are often too low a concentration to eliminate Pseudomonas spp.

Outbreaks of clinical mastitis associated with Nocardia spp. have been associated with the use of blanket dry cow therapy and the use of a specific neomycin-containing dry cow preparation. The mastitis pathogens, and their relative importance, continue to evolve as new management methods and control practices are developed. Thus, there is an ongoing need for epidemiological studies to characterize the pathogens and describe their association with the animals and their environment. Improved control methods can develop only from investigations into the distribution and pathogenic nature of the microorganisms isolated.

Etiology

Bovine mastitis is associated with many different infectious agents, commonly divided into those causing contagious mastitis, which are spread from infected quarters to other quarters and cows, those that are normal teat skin inhabitants and cause opportunistic mastitis, and those causing environmental mastitis, which are usually present in the cow's environment and reach the teat from that source. Pathogens causing mastitis in cattle are further divided into major pathogens (those that cause clinical mastitis) and minor pathogens (those that normally cause subclinical mastitis and less frequently cause clinical mastitis).

Major pathogens

Contagious pathogens
- S. agalactiae
- S. aureus
- M. bovis.

Environmental pathogens

Environmental Streptococcus species include S. uberis and S. dysgalactiae, which are the most prevalent; less prevalent is S. equinus (formerly referred to as S. bovis). The environmental coliforms include the Gram-negative bacteria E. coli, Klebsiella spp. and Enterobacter spp. A. pyogenes mastitis can be an important problem in some herds.

Minor pathogens

Several other species of bacteria are often found colonizing the teat streak canal and mammary gland. They rarely cause clinical mastitis and are known as minor pathogens. They include the coagulase-negative Staphylococcus spp. such as Staphylococcus hyicus and Staphylococcus chromogenes, which are commonly isolated from milk samples and the teat canal. Staphylococcus xylosus and Staphylococcus sciuri are found free-living in the environment; Staphylococcus warneri, Staphylococcus simulans and Staphylococcus epidermidis are part of the normal flora of the teat skin (and therefore are skin opportunistic pathogens). The prevalence of coagulase-negative Staphylococcus spp. is higher in first-lactation heifers than cows, and higher immediately after calving than in the remainder of lactation. In recent studies, they have been found as teat canal and intramammary infections in nulliparous heifers.

C. bovis is also a minor pathogen; it is mildly pathogenic and the main reservoir is the infected gland or teat duct. However, in some herds, C. bovis appears to be a common cause of mild clinical mastitis. C. bovis spreads rapidly from cow to cow in the absence of adequate teat dipping. The prevalence of C. bovis is low in herds using an effective germicidal teat dip, good milking hygiene and dry cow therapy. The presence of C. bovis in a gland will reduce the likelihood of subsequent infection with S. aureus.

Uncommon mastitis pathogens

Many other bacteria can cause severe mastitis, which is usually sporadic and usually affects only one cow or a few cows in the herd. These include Nocardia asteroides, Nocardia brasiliensis and Nocardia farcinica, Histophilus somni, Pasteurella multocida, Mannheimia (formerly Pasteurella) haemolytica, Campylobacter jejuni, B. cereus and other Gram-negative bacteria including Citrobacter spp., Enterococcus faecalis, Enterococcus faecium, Proteus spp., P. aeruginosa, and Serratia spp. Anaerobic bacteria have been isolated from cases of mastitis, usually in association with other facultative bacteria, e.g. Peptostreptococcus indolicus, Prevotella melaninogenica (formerly Bacteroides melaninogenicus), Eubacterium comitata, Clostridium sporogenes and Fusobacterium necrophorum.

Fungal infections include Trichosporon spp., Aspergillus fumigatus, Aspergillus nidulans and Picha spp.; yeast infections include Candida spp., Cryptococcus neoformans, Saccharomyces spp. and Torulopsis spp. Algal infections include Prototheca trispora and Prototheca zopfi.

Leptospirosis, including Leptospira interrogans serovar. pomona, and especially Leptospira interrogans hardjo, cause damage to blood vessels in the mammary gland and gross abnormality of the milk. They are more correctly classified as systemic diseases with mammary gland manifestations, and are described under those headings in the book.

Some viruses may also cause mastitis in cattle, but they are of little importance.

Epidemiology

This section deals with the general aspects of epidemiology of bovine mastitis. For information about the epidemiology of mastitis in the other animal species see the appropriate sections at the end of this chapter.
Occurrence and prevalence of infection

Occurrence refers to the location of the disease and the kinds of animals affected. Prevalence is the percentage of the population affected with a specific disease in a given population at a certain point in time. The incidence is a rate, such as the total number of new cases of clinical mastitis as a percentage of the animals at risk that occur during a certain period of time. Prevalence is a function of the incidence and the duration of infection.

Prevalence

In most countries, surveys in dairy herds indicate that the prevalence of infection of mastitis pathogens is approximately 50% of cows and 10–25% of quarters. The prevalence of infection in dairy heifers of breeding age and in pregnant dairy heifers varies widely from 30–50% of heifers and 18% of quarters to as high as 97% of heifers and 75% of quarters.

Incidence

The average annual incidence of clinical mastitis, calculated as the number of clinical quarter cases per 100 cows at risk per year, including the dry period, in individual herds ranges from 10–12% in most herds but higher incidences, ranging from 16–65%, occur in some herds. The greatest risk of first acquiring mastitis occurs early in lactation, usually in the first 50 days. The risk of clinical mastitis also increases with increasing parity. In beef herds, 32–37% of cows and 18% of quarters may have intramammary infection, which has a significant negative effect on calf weaning weights.

Case fatality rates vary widely depending largely on the identity of the causative organism. For example, S. agalactiae mastitis is not a fatal disease but peracute intramammary mastitis in a recently calved cow may often be fatal. Details of the occurrence of the different types of mastitis are presented in their individual sections in this chapter.

Relative prevalence of infection with intramammary pathogens

The prevalence of infection with intramammary pathogens in cattle is remarkably similar in different countries. The bacteriological identification of mastitis pathogens is important because control and eradication procedures depend on the kind of infection prevalent in the herd. In addition, the validity of epidemiological investigations aiming at determining transmission patterns or the impact of environmental and management factors to a large extent depends on exact bacteriological diagnosis.

Contagious pathogens

The prevalence of infection with S. aureus in cows ranges widely, usually from 7–40%, but higher in some herds. A survey of Danish dairy herds found that 21–70% of all cows and 6–35% of all quarters were infected. S. aureus was isolated from 10% of quarter samples and was the most common species isolated. The prevalence of streptococci, including S. agalactiae, ranges from 1–8% of cows. A relative incidence of S. agalactiae, other streptococci and S. aureus of 1:12 is a common finding. S. aureus may still assume some importance as a cause of subclinical mastitis but its prevalence has been reduced by modern mastitis control programs, leading to a higher proportion of culture-negative mastitic quarters and a corresponding, and perhaps consequent, increase in infections by E. coli and Klebsiella spp. The prevalence of infection due to Mycoplasma spp. varies widely.

The prevalence of infection due to an individual pathogen, and therefore the ratio between its incidence and that of other pathogens, depends on several risk factors such as size of herd and quality of management, especially milking parlor hygiene and cleanliness of accommodation, and parity of animal (heifer or cow). For example, large, zero-grazed herds kept in drylot conditions are likely to encounter more hygiene problems than conventionally housed herds mainly because of constant soiling of the udder by inadequate or improper bedding in larger units. In those circumstances there is likely to be a much higher prevalence than usual of mastitis associated with E. coli and S. uberis.

Teat skin opportunistic pathogens

Coagulase-negative staphylococcal species were found in 4.1% of samples; the most frequently isolated were S. epidermidis (1.3%), S. chromogens (1.0%) and S. simulans (0.7%).

Environmental pathogens

The prevalence of intramammary coliform infections in a dairy herd seldom exceeds 1–2%; the prevalence of intramammary environmental streptococci is less than 5% in well managed herds but may exceed 10% in some problem herds. A characteristic of intramammary coliform infections is the short duration: 40–50% persist less than 7 days. The majority of environmental streptococci infections last less than 30 days. In a survey of Danish dairy herds, S. dysgalactiae (1.6%) and S. uberis (1.4%) were the second and third most common species isolated.

Heifers

Surveys of intramammary infection of heifers in regions such as Louisiana indicate variable prevalence and duration of intramammary infection according to species of bacteria present around the time of parturition. About 20% of heifers were infected with S. aureus and 70% with coagulase-negative staphylococci, the minor pathogens that are part of the normal teat skin flora of heifers. S. chromogenes was isolated from 15% of all quarters of heifers before parturition but decreased shortly after parturition to 1%. Up to 97% of breeding age and pregnant dairy heifers and 75% of their quarters may be infected with S. aureus, S. hyicus and S. chromogenes. Infections with S. simulans and S. epidermidis occurred in 1–3% of quarters both before and after parturition. S. dysgalactiae was isolated from 4–6% of quarters before and immediately after parturition. Intramammary infections with S. aureus rarely occurred before parturition but increased during the first week after parturition. There was no association between the prevalence of S. aureus in heifers before parturition and the prevalence in lactating cows.

Distribution of pathogens in clinical mastitis

The distribution of pathogens isolated from cases of clinical mastitis has changed with the adoption of control programs from a high frequency of isolation of S. aureus and S. agalactiae to a higher isolation rate of other pathogens, particularly environmental mastitis pathogens. For example, in 171 randomly selected dairy herds, the average annual incidence of clinical mastitis was 12.7 quarter cases per 100 cows per year. The most frequent isolates from clinical cases were E. coli (16%), S. aureus (14%), S. uberis (11%), and S. dysgalactiae (8%). In another survey, the most common isolates from clinical cases were coagulase-negative staphylococci and E. coli, each at 15% of samples taken. In a 2-year observational study of 65 dairy herds in Canada, there was considerable variation in the incidence of clinical mastitis among farms. Overall, 20% of cows experienced one or more cases of clinical mastitis during lactation. The pathogens isolated were coagulase-negative staphylococci, E. coli, S. aureus (7%), Gram-positive bacilli (6%), C. bovis (2%), S. agalactiae (1%), and other Staphylococci spp. (29%). There was no growth in 18% of samples and 8% were contaminated. Clearly the main difference is that the rate of S. aureus in clinical cases is higher in continental Europe and lower in England and North America.

Source of infection

Contagious pathogens

S. agalactiae and S. aureus reside primarily in the udder of infected cows; the source of infection is other infected cows and exposure to uninflfected quarters is limited to the milking process.

Teat skin opportunistic pathogens

S. coagulase-negative staphylococci occur early in lactation, usually in the first 50 days. The risk of clinical mastitis also increases with increasing parity. In beef herds, 32–37% of cows and 18% of quarters may have intramammary infection, which has a significant negative effect on calf weaning weights.

Case fatality rates vary widely depending largely on the identity of the causative organism. For example, S. agalactiae mastitis is not a fatal disease but peracute intramammary mastitis in a recently calved cow may often be fatal.
Teat skin opportunistic pathogens
A number of species of coagulase-negative staphylococci reside primarily on the teat skin of cattle.

Environmental pathogens
*S. iberis*, *S. dysgalactiae*, and coliforms are common inhabitants of the cow's environment such as bedding. The exposure of uninfected quarters to environmental pathogens can occur at any time during the life of the cow, including milking time, between milkings, during the dry period and prior to first calving in heifers.

Methods of transmission
Infection of each mammary gland occurs via the teat canal, the infection originating from either an infected udder or the environment; in dairy cattle the infection originating from infected udders is transmitted to the teat skin of other cows by milking machine liners, milkers' hands, wash cloths and any other material that can act as an inert carrier.

Risk factors
Risk factors that influence the prevalence of infection and the incidence of clinical mastitis are outlined here. Individual factors that are of particular importance in the individual types of mastitis are described under those headings.

Animal risk factors

Age and parity
The prevalence of infected quarters increases with age, peaking at 7 years. Surveys of the prevalence of intramammary infection in dairy heifers a few days before their first parturition reveals that 45% are infected, and the quarter infection rate may be 18%. Some studies found intramammary infections in 97% of heifers and 74% of quarters.

Stage of lactation
Most new infections occur during the early part of the dry period and in the first 2 months of lactation, especially with the environmental pathogens. In heifers, the prevalence of infection is often high in the last trimester of pregnancy and several days before parturition, followed by a marked decline after parturition. In dairy heifers, most of these prepartum infections are associated with the minor pathogens but some surveys have found evidence of infection by the major pathogens. The mean prevalence of *S. aureus* intramammary infection in primiparous cows at first parturition in high prevalence herds can be as high as 30%, ranging from 13-65%, and in low prevalence herds it may as low as 2%, ranging from 0-5%. The overall prevalence of infection of *S. aureus* intramammary infection in primiparous cows at parturition was 8%, ranging from 0-27%. Of those cows with *S. aureus* intramammary infection at parturition, 43% had *S. aureus* intramammary infection at least 2 months after parturition. Primiparous cows with these infections may represent significant reservoirs of infection to uninfected animals in the herd.

Some of these differences may be related to changes in the milk as a medium for bacterial growth. For example, bacteria such as *C. bovis* grow best in milk secreted in the middle of lactation, whereas dry period secretion inhibits its growth. During the dry period the quarter's capacity to provide phagocytic and bactericidal activities diminishes.

Somatic cell count
The highest average incidence of clinical mastitis due to environmental bacteria may occur in herds with the lowest bulk tank milk SCC (< 150,000 cells/mL) and a low prevalence of subclinical infection.

Breed
Generally the incidence of mastitis is greater in Holstein-Friesians than in Jerseys, but this may reflect differences in management rather than a true genetic difference. Valid comparisons between breeds have not been reported.

Milkling characteristics and morphology of udder and teat
High milking rate and large teat canal diameter have been associated with increased SCC or risk of intramammary infection. Milk leaking in cows in herds with a low bulk tank milk SCC has also been associated with an increased rate of clinical mastitis. Decreasing teat-end-to-floor distance is also a risk factor for clinical mastitis and may be associated with an increased incidence of teat lesions. Heritability estimates of teat-end-to-floor distance or udder height range from 0.2-0.7, which may be a consideration in the selection indices of bulls. Periparturient udder edema may also be a risk factor for clinical mastitis.

Physical condition of teat
The teat end is the first barrier against invading pathogens, and the efficiency of teat defense mechanisms depends on the integrity of teat tissue; its impairment leads to an increase in the risk of intramammary infection. Teat thickness is an aid to evaluating teat tissue status. Milking machine characteristics can induce a decrease or increase in teat thickness after milking compared with premilking values. Increases in teat thickness of more than 5% are significantly associated with infection and new infection, but the association was not significant when teat thickness decreased by more than 5%. Coagulase-negative staphylococcal infections are significantly associated with both increases and decreases in teat thickness numerically greater than 5%, but there is no association between teat thickness and *S. aureus* infections.

Hyperkeratosis of the teat orifice is a commonly observed condition in the dairy cow because of machine milking; the degree of hyperkeratosis may be increased by a poor milking system. There is wide variation in the degree of hyperkeratosis between herds; the score increases with lactational age and peaks, for any lactation, at 3-4 months after parturition, declining as the cows dry off. There is no significant relationship between mean SCC and the degree of hyperkeratosis at the herd level.

Udder hygiene
Dirty udders are associated with increased SCC and an increased prevalence of intramammary infection due to contagious pathogens, but surprisingly are not associated with intramammary infections due to environmental pathogens. This suggests that udder hygiene is a proxy for general mastitis management skills, in that good mastitis control programs result in low prevalence of infection with contagious pathogens.

Nutritional status
Vitamins E and A and selenium may be involved in resistance to certain types of mastitis. Early reports found that supplementation with antioxidants such as selenium and vitamin E had a beneficial effect on udder health in dairy cattle by decreasing the incidence and duration of clinical mastitis. An increase in selenium concentration in whole blood was associated with a decrease in all infections, including *S. aureus*, *A. pyogenes*, and *C. bovis*. There was no association between different infections or SCC and concentrations of vitamin E, vitamin A, or beta-carotene, but an association existed between vitamin A concentration and SCC. The lower selenium concentration in whole blood did not increase the incidence of clinical mastitis.

Genetic resistance to mastitis
A variety of morphological, physiological and immunological factors contribute to a cow's resistance or susceptibility to mastitis, and each of these factors is influenced to some extent by heredity. Differences in udder depth, teat length, teat shape, and teat orifice morphology are thought to be associated with differences in mastitis. The production of keratin in the streek canal and the physical and biochemical characteristics of keratin are important contributors to mastitis resistance. Many of the defense mechanisms of the udder, including...
lysozyme, lactoferrin, immunoglobulins and leukocytes, are direct products of genes and have a genetic basis. For dairy cattle, heritability estimates for clinical mastitis average about 0.05. These low heritability estimates indicate that there is very little genetic influence on clinical mastitis but a very strong environmental influence.

**Somatic cell count** Differences in heritability between herds with high and low SCCs are not significant. However, differences among bulls' daughter groups for both clinical mastitis and SCC are reasonably large, suggesting that selection of sires can be important in mastitis control. An analysis of the disease and breeding records of a large number of Swedish bulls sireing daughters whose milk had a low SCC count found genetic correlations of 0.71–0.79 between SCC and clinical mastitis. It was concluded that it is possible to improve resistance to clinical mastitis by selecting for a low SCC.

The strong phenotypic and genetic association between SCC and mastitis indicates that breeding programs based on SCC may be effective as an indirect means of improving mastitis resistance. However, greater emphasis on SCC may decrease genetic gain in yield traits, which are economically more important.

**Milk yield**
The genetic correlation between milk yield and mastitis is about 0.2–0.3, which suggests that animals genetically above average for milk yield are more susceptible to mastitis and that low-yielding cows tend to be more resistant. However, the low correlation value suggests that this relationship is not a strong tendency. The positive correlation implies that genetic improvement for milk yield is accompanied by a slow decline in genetic resistance to mastitis. Examination of the association between milk yield and disease in a large number of dairy cows found that higher milk yield was not a factor for any disease except mastitis. However, the association between milk yield and mastitis does not imply causation. At least two biological explanations are plausible: increased injury and leaking of milk between milkings. Improved mastitis control efforts have offset the genetic trend for increased susceptibility to mastitis. The low heritability for mastitis indicates the great importance of environmental factors in causing differences in the prevalence of infection and the incidence of clinical mastitis.

In summary, selection for milk yield alone results in increased incidence of mastitis. The positive genetic correlation between milk yield and mastitis suggests that genes that increase milk yield tend to increase susceptibility to mastitis. Selection indices that maximize genetic improvement for net economic benefit will not decrease the incidence of mastitis, but indices that include SCC, udder depth or clinical mastitis will diminish the rate of increase in mastitis by 20–25%. Using **predicted transmitting ability** (PTA), an estimate of genetic merit, it has been found that on average that daughters of bulls with high PTAs for SCC have a higher incidence of mastitis; sires with low PTA for somatic cell scores should therefore be selected. All of the economically important traits are weighted into a selection index for the selection of bulls which will improve net income over cost of production.

**Other concurrent diseases**
These may be important risk factors for mastitis. Retained placentas, teat injuries and teat sores may be associated with a higher incidence of mastitis. Sole ulceration of any severity occurring in more than one digit has been associated with an approximately threefold higher risk of *S. aureus* infections in the first lactation. It is suggested that sore feet could increase the risk of teat lesions, presumably as a result of difficulty in standing.

**Immunological function of mammary gland**
The immune function of the mammary gland is impaired during the periparturient period; it is susceptible to mastitis during transition periods, such as drying off and colostrogenesis. As a result, the **incidence of new intramammary infections** is highest during the early nonlactating period and the periparturient period.

The most important components of the defense against common bacterial pathogens are blood-derived **neutrophils** and **opsonizing antibodies**. An inadequate rate of neutrophil recruitment to combat a new intramammary infection has a profound effect on the outcome of infection, in that cows with a rapid and massive recruitment of neutrophils to an infected gland clear an intramammary infection within 12–18 hours postinfection.

It is also important that an early inflammatory response in the infected mammary gland enables leakage of IgG, (opsonizing antibodies) as this facilitates neutrophil phagocytosis of bacteria. The **staggered one–two punch of peak IgG concentrations** within 4 hours of infection and **peak neutrophil response** within 6–12 hours of infection greatly facilitates clearance of new intramammary infections.

Blood-derived neutrophils must undergo **margination, adherence and migration** in order to arrive in the mammary gland, where they perform **phagocytosis**, **respiratory burst and degranulation**. Margination is via expression of three adhesion molecules from the selectin family, specifically L-selectin (also called CD62L) on neutrophils, E-selectin (also called CD62E), and P-selectin (also called CD62P) on vascular endothelial cells. Neutrophil L-selectin makes the initial contact between 'streaming' neutrophils in the blood stream and the vascular wall; this contact slows neutrophil movement and allows them to 'roll' along the endothelium while surveying for the presence of proinflammatory mediators at the sites of tissue infection. When the rolling neutrophils detect the presence of one or more proinflammatory mediators they immediately shed surface L-selectin (CD62L) adhesion molecules and up-regulate and activate Mac-1 (CD11b/CD18) adhesion molecules, thereby stopping neutrophil rolling and permitting tight adherence of the neutrophil to the endothelium. Once adhered, neutrophils commence diapedesis by migrating between endothelial cells to the site of infection. Neutrophil migration therefore has three components: hyperadherence (cessation of rolling), diapedesis and chemotaxis. Any delay or inhibition in this process can lead to peracute mastitis and severe clinical disease. This is best illustrated by bovine leukocyte adhesion deficiency (BLAD) in Holstein–Friesian cattle; affected calves cannot produce Mac-1 molecules and have a prominent neutropenia because streaming neutrophils cannot migrate to the site of infection. Migration of neutrophils is slow during the first few weeks of lactation and this delay in neutrophil migration is believed to be responsible for the increased incidence and severity of intramammary infections during early lactation.

**Preceding mastitis**
Cows with a history of mastitis in the preceding lactation are almost twice as susceptible to clinical mastitis in the current lactation as those without mastitis in the preceding lactation.

**Pre-existing intramammary infections**
Natural infection with minor pathogens has a protective effect against infections with major pathogens. The lowest rate of infection with major pathogens has been observed in quarters infected with *C. bovis*. Elimination of these minor pathogens with postmilking teat disinfection may result in an increase in the incidence of clinical mastitis. Discontinuation of the teat dipping may be associated with an increase in the prevalence of minor pathogens, increase in the incidence of *S. aureus* infections, and decrease in the incidence of *E. coli* infections. Thus quarters already infected with
a minor or major infection are less likely to acquire a new infection than uninfected quarters.

Use of recombinant bovine somatotropin
Because the risk of clinical mastitis increases as milk production increases, there has been considerable scientific and public controversy over the potential effects that the use of recombinant bovine somatotropin (bST) might have on the incidence of clinical mastitis and the subsequent use of antimicrobials from therapy. In some field trials, the use of bST did not result in an increase in the incidence of clinical mastitis compared to controls. In other trials, a significant increase in the incidence of clinical mastitis occurred in treated cows compared to controls. However, the incidence of clinical mastitis was greater in treated cows compared to controls before bST was used. In trials done on well managed farms which had controlled contagious mastitis and had low rates of clinical mastitis due to environmental pathogens, the use of bST was not associated with an increase in clinical mastitis, discarded milk because of therapy or culling for mastitis. Interpretation of a direct effect of bST on mastitis incidence is confounded by the higher incidence of mastitis in cows of higher milk production.

Environmental and management risk factors
Quality and management of housing
Factors such as climate, housing system, type of bedding and rainfall interact to influence the degree of exposure of teat ends to mastitis pathogens. Because dairy cattle spend 40–65% of their time lying down, the quality and management of housing for dairy cattle has a major influence on the types of mastitis pathogens that infect the mammary gland, as well as the degree of infection pressure.

The major sources of environmental pathogens are the cow's environment, including bedding, soil, feedstuffs and water supplies. Environmental pathogens multiply in bedding materials, with which the cow's teats are in close and prolonged contact. Bacterial growth in bedding depends on temperature, amount of moisure and nutrients available, and the pH. Fresh bedding can be a source of contamination even before it is used: Klebsiella pneumoniae can be present in green, hardwood sawdust in higher numbers than in other types of bedding and major outbreaks of environmental mastitis due to K. pneumoniae have occurred following the use of contaminated wood products bedding, described in detail in that section. Dry, unused bedding contains few pathogens but after being used it becomes contaminated and provides a source in which pathogens multiply to high numbers in 24 hours. Organic bedding materials such as straw, sawdust, wood shavings and paper support the growth of pathogens. Inorganic materials such as sand retain less moisture and do not provide a supply of nutrients for the pathogens; bacterial counts in these materials are usually lower than in organic materials. Housing lactating cow on sawdust leads to six times more Klebsiella bacteria and twice as much coliform bacteria on the teat ends compared to housing cattle on sand. In contrast, there were 10 times more environmental streptococci bacteria on teat ends when cows were housed on sand, compared to housing on sawdust.

High humidity and high ambient temperatures favor growth of pathogens. Cows in confinement housing with organic bedding materials have the highest incidence of environmental mastitis in the warm, humid months of the year. Pasturing herds during the summer months usually reduces the incidence of coliform mastitis, although rates of environmental streptococci may remain high. In drylot systems the incidence of coliform mastitis may be associated with periods of high rainfall. Herds with more months on pasture may have a higher incidence of clinical mastitis, which may be associated with factors such as sanitation and the stress of transition between pasture and confinement housing.

The management and design of housing systems influence the prevalence of intramammary infection and the incidence of clinical mastitis. Any housing factor or management system that allows cows to become dirty or damage teats or that causes overcrowding will result in an increase in clinical mastitis. This includes the size and comfort of free stalls, the size of the alleyways, ease of movement of cattle and the cleaning system. Failure to keep alleyways, cow stalls and bedding clean and dry will increase the level of contamination of the teats. Overcrowding, poor ventilation, access to dirty ponds of water and muddy areas where cows congregate are major risk factors.

The size of the milking cow herd may be positively associated with an increased incidence of clinical mastitis because it can be more difficult to control contagious mastitis in a herd with a greater prevalence of infection and a larger number of cow-to-cow contacts. As herd size increases, manure disposal and sanitation problems may increase exposure to environmental pathogens. However, regional and management differences may confound the association of size with infection status. Some recent data suggest lower SCC in large herds. The use of designated maternity areas providing an isolated and clean environment for parturition may be associated with a lower incidence of clinical mastitis.

If hygiene and bedding maintenance are neglected in the housing accomodation the prevalence of environmental forms of mastitis may increase markedly. Periodic inspection of dry cows is an essential part of mastitis control.

Milking practices
The failure to employ established and reliable methods of mastitis control is an important risk factor. This is a major subject, which includes efficiency of milking personnel, milking machines, high milking speed and especially hygiene in the milking parlor. Wet teats and udders are a risk factor for increased SCC, especially in the presence of teat impacts from liner slippage. The use of a separate drying cloth for each cow is associated with a lower SCC. Effective use of a postmilking germical teat dip is critical for the control of contagious mastitis. Increasing person-hours spent milking per cow may be associated with a higher rate of clinical mastitis. Contaminated milking equipment – including milk hoses, udder wash towels and teat dip products – has been associated with outbreaks of environmental mastitis from S. marcescens and P. aeruginosa. Drying off procedures at the end of lactation and an active policy on drying off treatment are equally important.

The absence of milk quality regulations that place emphasis on SCC is also a risk factor. Conversely, the presence of strict regulations with penalties for high SCC is an important incentive to institute mastitis control programs that improve the quality of milk. The absence of a health management program consisting of regular farm visits by the veterinarian may also be a risk factor for mastitis, which may be associated with a relative lack of awareness by the producer of the importance of the principles of mastitis control.

Season of year
The relationship between the incidence of mastitis and season of the year is variable, depending on geographical and climatic conditions. In subtropical and tropical areas the incidence may be higher during winter or spring calvings from the increase in infection pressure associated with increased humidity. In temperate climates, the incidence of mastitis is higher in autumn and winter, when calving occurs along with an extended period of housing.
Under conditions of housing for long winter periods, infectious agents are most likely to be found in higher numbers in the bedding. In the UK there is an increased frequency of mastitis when cows are housed for the winter.

Pathogen risk factors
Viability of pathogens
The ability of the pathogen to survive in the cow’s immediate environment (resistance to environmental influences including cleaning and disinfection procedures) is a characteristic of each pathogen. The causes of contagious mastitis are more susceptible to disinfection than the causes of environmental mastitis.

Virulence factors
There is a wide variety of virulence factors among the mastitis pathogens. These are described under specific mastitides. The influence of many bacterial virulence factors depends on the stage of lactation and severity of the intramammary infection and the effects elicited by the virulence factors on bovine mammary tissue. A few examples of the common virulence factors are noted here.

Colonizing ability
The ability of the pathogens to colonize the teat duct, then to adhere to mammary epithelium and to initiate mastitis is a major characteristic of the major bacterial causes of mastitis. *S. aureus* strains that cause mastitis can bind to ductular udder epithelial cells and to explant cultures of bovine mammary tissue. There are differences in the adhesion characteristics among strains of the organism, which may explain the different epidemiological characteristics of the organisms in some herds. Comparison of strains isolated from different *S. aureus* mastitis cases between herds reveals that only a limited number of genotypes of *S. aureus* are most prevalent.

Toxins
*E. coli* isolates that cause mastitis produce lipopolysaccharide endotoxin, which is responsible for many of the inflammatory and systemic changes observed during acute coliform mastitis. *S. aureus* isolated from intramammary infections produces many potential virulence factors, including enterotoxins, coagulase and alpha, beta, delta toxins, hemolysin, hyaluronidase and leukocidin, which are considered to be involved in the varying degrees of inflammatory characteristic of staphylococcal mastitis from subclinical to peracute gangrenous mastitis. Virulence factors of *S. uberis* include hyaluronidase and the hyaluronic capsule.

Production and economic losses
Although mastitis occurs sporadically in all species, it assumes major economic importance in dairy cattle and may be one of the most costly diseases in dairy herds. Mastitis results in economic loss for producers by increasing the costs of production and by decreasing productivity. The premature culling of potentially profitable cows because of chronic mastitis is also a significant loss. Because of the large economic losses, there is a potential for high returns on investment in an effective control program. The component economic losses can be divided into:

- Loss of milk production
- Discarded milk from cows with clinical mastitis and treated cows
- Replacement cost of culled cows
- Extra labor required for treatment and monitoring
- Veterinary service for treatment and control
- Cost of first trimester abortions due to clinical mastitis
- Cost of control measures.

There are additional costs such as antimicrobial residues in milk from treated cows, milk quality control, dairy food manufacturing, nutritional quality of milk, degrading of milk supplies due to high bacteria or SCC, and interference with the genetic potential of some cows from early involuntary culling because of chronic mastitis. The total annual cost of mastitis in the dairy cattle population is estimated to be 10% of the total value of farm milk sales, and about two-thirds of this loss is due to reduced milk production in subclinically affected cows.

The production and economic losses are commonly divided into those associated with subclinical and clinical mastitis.

Subclinical mastitis
Total milk losses from quarters affected with subclinical mastitis have been estimated to range from 10–26%. Lower SCCs are associated with higher milk production, and rolling herd average milk production has been estimated to decrease by 190 kg per unit increase of linear somatic cell score. Most estimates indicate that on average an affected quarter results in a 30% reduction in productivity, and an affected cow is estimated to lose 15% of its production for the lactation. This loss is sometimes expressed as a loss of about 340 kg of saleable milk, due to loss of production and the value of milk that has to be withheld from sale. The loss in production by an infected quarter may be largely compensated by increased production in the other quarters so that the net loss from the cow may be less than expected. In addition to these losses, there is an added loss of about 1% of total solids by changes in composition (fat, casein, and lactose are reduced and glycogen, whey proteins, pH, and chlorides are increased), which interferes with manufacturing processes, and other losses include increased culling rates and costs of treatment. Comparisons between low- and high-prevalence herds always show a financial advantage of about 20% to the low-prevalence herds, the gain varying with the local price of milk or butter fat. In beef herds the losses are in the form of rare deaths of cows and failure of the calves to gain weight.

Approximately 75% of the economic loss from subclinical mastitis is attributable to loss of milk production. Other costs include discarding milk from treated cows, drug costs, veterinary costs, labor and loss of genetic potential of culled cows.

Clinical mastitis
Clinical mastitis results in marked decreases in milk production, which are much larger in early than late lactation. Milk production losses are also greater in cows with multiple lactations than first-lactation cows, and clinical mastitis also decreases the duration of lactation and increases the likelihood of culling. Clinical cases of brief duration that occur after the peak of lactation affect milk production very little but can induce abortion during the first 45 days of gestation. Clinically affected quarters may not completely recover milk production in subsequent lactations but these carry-over losses are not as large as the losses from acute mastitis. In the National Animal Health Monitoring System of dairy herds in the US, clinical mastitis alone was the most costly disease identified, at a loss to the producer of $27–50 per cow per year.

The costs of clinical mastitis and mastitis prevention in dairy herds have been estimated, based on monitoring 50 dairy herds over 1 year. Mean incidence of clinical mastitis was 39 cases/100 cow-years; each clinical case cost $38/cow-year. Lost milk production was estimated at $14.50/cow-year, which does include the losses associated with subclinical mastitis.

The component causes of economic loss associated with mastitis outlined above vary according to the causative pathogen and are described under specific mastitides. In general terms *S. aureus* and *E. coli* may cause death from peracute mastitis; *A. pyogenes* causes complete loss of quarters; staphylococci and streptococci cause acute clinical mastitis, but their principal role is in causing subclinical mastitis, resulting in a reduction of milk produced and a downgrading of its quality.
quality. Of these, *S. agalactiae* causes the greatest production loss, whereas *S. aureus* has the higher infection rate, greater resistance to treatment and longer duration of infection. At one time *S. aureus* represented the impassable barrier to mastitis control programs.

Other factors that affect the magnitude of the loss associated with mastitis include age (the loss is greatest in mature cows), and when the attack occurs in the first 150 days of lactation.

Zoonotic potential

With mastitis there is the danger that the bacterial contamination of milk from affected cows may render it unsuitable for human consumption by causing food poisoning, or interfere with manufacturing processes or, in rare cases, provide a mechanism of spread of disease to humans. Tuberculosis, streptococcal sore throat and brucellosis may be spread in this way. Raw (unpasteurized) milk can be a source of food-borne pathogens, and consumption of raw milk can result in sporadic disease outbreaks. For instance, sampling bulk tank raw milk in Ontario revealed the presence of *Listeria monocytogenes*, *Salmonella* spp., *Campylobacter* spp. or verotoxigenic *E. coli* in 2.7%, 0.2%, 0.5% and 0.9% of milk samples, respectively. These findings emphasize the importance of continued diligence in the application of hygiene programs within dairies and the separation of raw from pasteurized milk and milk products.

PATHOGENESIS

Infection of the mammary gland always occurs via the teat canal and on first impression the development of inflammation after infection seems a natural sequence. However, the development of mastitis is more complex than this and can be most satisfactorily explained in terms of three stages: *invasion, infection, inflammation*. Of the three phases, prevention of the invasion phase offers the greatest potential for reducing the incidence of mastitis by good management, notably in the use of good hygienic procedures.

**Invasion** is the stage at which pathogens move from the teat end to the milk inside the teat canal.

**Infection** is the stage in which the pathogens multiply rapidly and invade the mammary tissue. After invasion the pathogen population may be established in the teat canal and, with this as a base, a series of multiplications and extensions into mammary tissue may occur, with infection of mammary tissue occurring frequently or occasionally depending on its susceptibility. Multiplication of certain organisms may result in the release of endotoxins, as in coliform mastitis, which causes profound systemic effects with minimal inflammatory effects.

**Inflammation** follows infection and represents the stage at which clinical mastitis occurs with varying degrees of clinical abnormalities of the udder and variable systemic effects from mild to peracute; gross and subclinical abnormalities of the milk appear. Abnormalities of the udder include marked swelling, increased warmth and, in acute and peracute stages, gangrene in some cases and abscess formation and atrophy of glands in chronic stages. The systemic effects are due to the mediators of inflammation. Gross abnormalities of the milk include a decrease in milk yield, the presence of the products of inflammation and marked changes in the composition of the milk.

The most significant subclinical abnormality of the milk is the increase in the *somatic cell count*, the most common measurement of milk quality and udder health. Milk somatic cells in a healthy udder are few, but if inflammation occurs the number of somatic cells increases. In first lactation cows and dairy cows with short lactations, milk somatic cell numbers are less than 100,000 cells/mL (10^5), whereas in cows with long lactations, milk somatic cell numbers can increase to more than 1,000,000 cells/mL (10^6). The number of milk somatic cells is critically related to the promptness of the neutrophil migratory response and their bactericidal activity at the site of infection. As they colonize and multiply in the mammary gland, some bacteria release metabolic byproducts or cell-wall components (endotoxin if a Gram-negative bacteria) that serve as chemoattractants for leukocytes. If neutrophils move rapidly from the blood stream and are able to eliminate the inflammatory stimuli (bacteria), then recruitment of neutrophils ceases and the SCC returns to normal levels. If bacteria are able to survive this immediate host response, then the inflammation continues, resulting in neutrophil migration between adjacent mammary secretory cells toward the alveolar lumen. Prolonged diapedesis of neutrophils damages mammary tissue, resulting in decreased milk production. The duration and severity of the inflammatory response therefore has a major impact on the quantity and quality of milk produced.

The major factor affecting the SCC at the herd and individual cow level is the prevalence of intramammary infection at a glandular level. Because marked increases in SCC are a result of cells being attracted to the mammary tissue because of the mediators produced during a local infection, events that do not affect udder health are unlikely to have a direct or dramatic effect on SCC. Little evidence exists that any factor other than normal diurnal variation has a major influence on SCC in the absence of intramammary infections.

The effects of mastitis on milk yield are highly variable and depend on the severity of the inflammation, the causative agents and the lesions produced, the efficiency of treatment, the production level and the stage of lactation. Mastitis in early lactation causes a larger decrease in milk yield with long-term effects than mastitis in late lactation. Mastitis due to *S. aureus* generally evolves into persistent but moderate infections, unlike those associated with coillfors. Mastitis associated with *A. pyogenes* results in suppurative lesions, poor response to treatment and culling. *M. bovis* causes chronic induration and almost complete loss of milk production without recovery.

CLINICAL FINDINGS

Details of the clinical findings are provided under each specific type of mastitis. The clinical findings should be used only as a guide because different pathogens can cause chronic, subclinical, subacute, acute and peracute forms of the disease, and clinical differentiation of the different causes of mastitis is difficult. The greatest clinical accuracy achievable, even in a specialist hospital environment and after adaptation to suit local conditions, is about 70%, which is not sufficiently accurate to be clinically useful. In other words, bacteriological culture of milk from an affected gland is required before specific pathogen-directed treatment can be implemented.

Clinical mastitis is detected using only the results of the physical examination, and a useful definition of clinical mastitis is a negative answer to the question 'would you drink this?' In other words, 'undrinkable' is a simple and generalizable concept for defining clinical mastitis, in that milk from cows with clinical mastitis is not suitable for drinking. New cases of
Clinical mastitis are defined as being separated by at least 14 days.

The clinical findings in mastitis include abnormalities of secretion, abnormalities of the size, consistency and temperature of the mammary glands and, frequently, a systemic reaction. In other words, there are three categories of clinical mastitis: abnormal milk, abnormal gland and an abnormal cow (systemic disease). Abnormal milk is visibly abnormal (i.e. is not 'drinkable'). An abnormal gland is larger and firmer than other quarters. An abnormal cow is pyrexic, depressed or has decreased appetite or milk production. This three-part categorization scheme has excellent clinical utility, and readily occurs in many practical test situations. However, it may be difficult to categorize individual cows because of the small size of the milk during the first few days after calving, especially in heifers. These first few streams may be of less clinical significance because of the small size of the milk during the first few days after calving, especially in heifers.

During the dry period in normal cows, the secretion changes from normal milk to a clear watery fluid, then to a secretion and consistency of honey, and finally to colostrum in the last few days before parturition. Some variation may occur between individual quarters in the one cow; if this is marked, it should arouse suspicion of infection.

The strip cup provides a valuable tool to detect clinical mastitis and constitutes part of the routine physical examination of the lactating cow. The most sensitive use of the strip cup is to observe the ability of milk from one quarter to mix with milk from another quarter; incomplete mixing (evidence of 'streaming') indicates that secretions from the two quarters differ and suggests the presence of an intramammary infection in one of the quarters. However, it should be remembered that the strip cup can only detect clinical mastitis, and detection of subclinical mastitis requires use of indirect tests such as SCC of composite milk samples from individual cows, or application of the California Mastitis Test to quarter samples or measuring the electrical conductivity of quarter samples.

Abnormal gland

Abnormalities of size and consistency of the quarters may be seen and felt. Palpation is of greatest value when the udder has been recently milked, whereas visual examination of both the full and empty udder may be useful. The udder should be viewed from behind and the two hind quarters should be examined for symmetry. By lifting up the hind quarters, the fore quarters can be viewed. A decision on which quarter of a pair is abnormal may depend on palpation, which should be carried out simultaneously on the opposite quarter of the pair. Although in most forms of mastitis the observed abnormalities are mainly in the region of the milk cistern, the whole of the quarter must be palpated, particularly if the quarter is infected. The teats should be inspected and palpated for skin lesions, especially around the teat end. The supramammary lymph nodes should also be palpated for evidence of enlargement.

Palpation and inspection of the udder are directed at the detection of fibrosis, inflammatory swelling and atrophy of mammary tissue. Fibrosis occurs in various forms. There may be a diffuse increase in connective tissue, giving the quarter a firmer feel than its opposite number and usually a more nodular surface on light palpation. Local areas of fibrosis may also be palpated in a quarter; these may vary in size from pealike lesions to masses as large as a fist. Acute inflammatory swelling is always diffuse and is accompanied by heat and pain and marked abnormality of the secretion. In severe cases there may be areas of gangrene, or abscesses may develop in the glandular tissue. The terminal stage of chronic mastitis, atrophy of the gland. On casual examination an atrophied quarter may be classed as normal because of its small size, while the normal quarter is judged to be hypertrophic. Careful palpation may reveal that, in the atrophic quarter, little functioning mammary tissue remains.

Abnormal cow (systemic response)

A systemic response including toxemia, fever, tachycardia, ruminal stasis, depression, recumbency and anorexia may or may not be present, depending on the type and severity of the infection. A systemic response is usually associated with severe mastitis associated with E. coli, Klebsiella spp. or Staphylococcus spp. and occasionally with Streptococcus spp. or Staphylococcus spp. Clinical mastitis episodes due to A. pyogenes produces the greatest decrease in milk production. In contrast, clinical mastitis due to environmental streptococci and coagulase-negative staphylococci is associated with the smallest decrease in milk production. Clinical mastitis episodes due to S. aureus are associated with the highest risk of culling.

Diagnosis

Detection of clinical mastitis

The initial diagnosis of clinical mastitis is made during the routine physical examination. Laboratory culturing of milk samples for bacteria and Mycoplasma spp., and for determining the antimicrobial susceptibility of S. aureus (specifically whether it produces beta-lactamase), is very useful for instituting appropriate treatment. Therapeutic treatment protocols for cows with clinical mastitis and for instituting appropriate control measures.
However, because subclinical mastitis has the greatest influence on the cost of mastitis to the producer, it is advantageous to also diagnose subclinical mastitis, on a cow and quarter level.

Detection of subclinical mastitis
Culturing large numbers of milk samples, although the gold standard for intramammary infection and subclinical mastitis, is expensive and impractical for routine use. Much attention has therefore been given to the development of indirect tests to predict the presence of an intramammary infection. Currently available indirect tests detect only the presence of inflammation but are of value as screening tests; milk from quarters or cows with a positive screening test are then submitted to bacteriological culture. Subclinical mastitis can only be detected by laboratory examination and cannot, by definition, be detected during the routine physical examination. In other words, the secretion from a quarter with subclinical mastitis appears drinkable.

Detection at the herd level
The prevalence of subclinical mastitis or intramammary infection is monitored by determining the bulk tank milk SCC and the most likely mastitis pathogens are identified by culturing bulk tank milk. These two methods are recommended to diagnose the presence and prevalence of mastitis pathogens on a herd basis.

Bulk tank milk somatic cell counts
The SCC of bulk tank milk is an indirect measure of the prevalence of mastitis within a dairy herd. The SCC is increased primarily, but not exclusively, because of subclinical mastitis associated with Gram-positive bacterial intramammary infections. There is a good correlation between the number of streptococci (S. agalactiae, S. dysgalactiae, and S. uberis) colony-forming units found in bulk tank milk and its SCC. The number of colony forming units (cfu) of S. aureus is moderately correlated to the bulk tank milk SCC. As contagious mastitis has become more effectively controlled, environmental mastitis pathogens have become a relatively more important cause of high SCC in bulk tank milk, especially in herds with moderate (<400 000 cells/mL) to low (<150 000 cells/mL) bulk tank milk SCC.

The association between management practices, dairy herd characteristics and SCC of bulk tank milk has been examined in about 60 000 cows in 843 herds over a 2-year period. Results indicated that the prevalence of S. agalactiae and S. aureus intramammary infections was associated with bulk tank SCC. In herds free of S. agalactiae mastitis, the prevalence of S. aureus and C. bovis intramammary infections were correlated with bulk tank SCC. For herds without S. agalactiae, use of sawdust bedding was associated with a decrease in SCC in bulk tank milk, while a dirty loose housing area was associated with an increase in SCC in bulk tank milk. Increased milk production, repeated mastitis control visits and use of particular preprod compounds were significantly associated with decreased SCC in bulk tank milk in all herds, regardless of whether any cows in the herd had S. agalactiae mastitis. In herds with S. agalactiae mastitis, use of iodine, chlorhexidine, peroxide or sodium chloride–lactic acid as a preprod was associated with a decrease in SCC of bulk tank milk.

The SCC of bulk tank milk has become a widely used test because it provides a sensitive and specific indicator of udder health and milk quality. The sample for analysis is obtained by agitating the milk for 5–10 minutes and collecting a sample from the top of the bulk tank milk using a clean dipper. The sample should not be collected near the outlet valve because this varies from that in the rest of the tank. The SCC of bulk tank milk is widely used to regulate whether the sample for examination be taken that the sample for examination be taken

It is not possible to use the bulk tank milk SCC to determine the number of cows in a herd affected by mastitis but it is possible to estimate fairly accurately the number of infected quarters. In general, as the bulk tank milk SCC increases, the prevalence of infection increases and losses in production increase. Production losses calculated as a percentage of production expected with a count of 200 000 cells/mL are shown in Table 15.1. A bulk tank milk SCC of more than 300 000 cells/mL is considered to indicate a level of mastitis in the herd that warrants examination of individual cows. Herds with a high bulk tank milk SCC have significantly lower production levels and are less likely to use a postmilking teat dip or to have a regular program of milking machine maintenance or automatic cluster removal.

Culture of bulk tank milk
Bacteria present in bulk tank milk may originate from infected udders, from teat and udder surfaces or from a variety of other environmental sources; however, despite the large number of potential sources for bacteria, culture of bulk tank milk is a useful technique for screening for major mastitis pathogens. The culture of S. aureus and S. agalactiae from bulk tank milk is a reliable indicator of infection by those pathogens in the herd. The number of those pathogens found on culture is determined by the number of bacteria shed, the number of infected cows, the milk production level of infected cows relative to herd mates, and the severity of infection. A single culture of bulk tank milk has low sensitivity but high specificity for determining the presence of S. agalactiae or S. aureus in the herd. Thus many infected herds will be called negative but few uninfected herds will be called positive. Pathogens such as Nocardi spp. and Mycoplasma spp. have also been identified by culture of bulk tank milk. In general, the sensitivity of a single bulk tank milk culture to detect the presence of intramammary infections due to S. agalactiae ranges from 21–77%, for S. aureus it ranges from 9–58% and for M. bovis it is 33%.
Environmental bacteria such as *S. uberis*, *S. dysgalactiae*, and coliforms may enter milk from intramammary infections, but also from nonspecific contamination. The presence of these organisms in bulk tank milk may relate to the general level of environmental contamination and milking hygiene in the herd. Udder infections with these environmental pathogens are predominantly of short duration and characterized by clinical disease, which makes their inadvertent introduction to the bulk tank less likely.

**String sampling** or milk line sampling from the positive pressure side of the milking system is the collection of milk samples from a group of cattle instead of the entire herd, as in bulk tank milk sampling. String sampling may have some merit in identifying subgroups of cattle with the highest prevalence of contagious pathogens than bulk tank milk sampling. If a production group tests positive on a string culture, then individual composite milk cultures can be performed to identify individual animals. Information of the culture results from string sampling should assist development of control programs; however, milk samples left in the pipeline from one string can confound the culture results of subsequent strings.

Numerous bacteriological techniques have been used to isolate and identify pathogens in bulk tank milk but none has been established as the gold standard method for the culture of milk from bulk tanks. The most suitable laboratory medium for growth and classification of the pathogens from bulk tank milk needs to be assessed. Sampling strategies have included weekly and monthly samples, but it remains to be determined which strategy is optimal relative to herd size and management, disease characteristics and practicality.

**Culture of bulk tank milk** has been compared to bulk tank SCC, herd summaries of SCC of individual cows and herd summaries of cultures of individual cows. A significant correlation was found between bulk tank SCC and the frequency of isolating *S. agalactiae* from monthly samples of bulk tank milk. The correlations between *S. aureus* from bulk tank milk and SCC are lower.

**Detection at the individual cow level** Abnormalities of the udder and gross abnormalities of milk in cattle with clinical mastitis have been described above under clinical findings. In individual cows with clinical mastitis, culture of the secretion from an infected quarter can be done. In animals without clinical mas-

- titis, culture of the secretion represents a direct test for subclinical mastitis. The objective is to identify cows with contagious mastitis so that they can be treated or culled, or to identify the nature and source of environmental mastitis pathogens. Fulfillment of these requirements requires bacteriological culture of milk samples so that the pathogens can be named; **identification of mastitis pathogens is central to the development of effective treatment and control programs**. Detection of infected cows requires an individual cow examination and application of an indirect (screening) test for infection, such as the SCC of a composite milk sample, followed by culture of a representative subset of cows in order to determine the most prevalent pathogen. **Indirect tests estimate the prevalence of infection and microbiological examination identifies the mastitis pathogens**; from this information an appropriate control plan can be formulated.

**Culture of individual cow milk**

- Individual cow milk can be cultured as part of a herd examination for mastitis, or on individual quarter samples, or on composite samples including milk from all four quarters. An intramammary infection is defined as the presence of the same pathogen in two of three consecutive cultures obtained on different sampling dates. **Individual quarter samples are preferred** because the costs of treatment dictate that the least possible number of quarters be treated. With this technique only affected quarters are treated; if the quarter infection rate is low the saving in treatment costs is relatively large.

- Milk sampling for culture must be carried out with due attention to cleanliness since samples contaminated during collection are worthless. The technique of cleaning the teat is of considerable importance. If the teats are dirty, they must be washed and then properly dried or water will run down the teat to the teat end and infect the milk sample. The end of the teat is cleaned with a swab dipped in 70% alcohol, extruding the external sphincter by pressure to insure that dirt and wax are removed from the orifice. Brisk rubbing is advisable, especially of teats with inverted ends. The first two or three streams are rejected because their cell and bacterial counts are likely to be a reflection of the disease situation within the teat rather than within the udder as a whole. The next few streams, the premilking sample, is the approved one because of its greater accuracy. For complete accuracy a premilking and a postmilking sample are taken. If tuberculosis is suspected, the last few streams are the critical ones. Indirect and chemical tests for mastitis can be carried out as accurately on foremilk as on later milk.

- If individual quarter samples are collected, screw-cap vials are most satisfactory. During collection the vial is held at an angle to the ground in order to avoid as far as possible the entrance of dust, skin scales and hair. If there is delay between the collection of samples and laboratory examinations, the specimens should be refrigerated or frozen. Freezing of milk samples appears to have variable effects on bacterial counts, depending on the bacteria. *A. pyogenes* and *E. coli* counts are decreased by freezing, coagulase-negative *Staphylococcus* spp. counts are increased, and *Streptococcus* and *S. aureus* counts are either unaffected or increased by about 200%.

- The laboratory techniques used vary widely and depend to a large extent on the facilities available. Incubation on blood agar is most satisfactory; selective media for *S. agalactiae* having the disadvantage that other pathogens may go undetected. Smears of incubated milk are generally unsatisfactory as not all bacteria grow equally well in milk. An augmented system of culturing milk samples, which has given superior results in terms of the number of infected quarters detected, includes preculture incubation, then freezing of the milk sample, then inoculation of the medium with a larger than normal inoculum of milk. The concern with augmented culture systems is that they may amplify contaminants obtained during sampling and therefore decrease the specificity of milk culture. Laboratory culturing techniques can be very time-consuming and expensive unless modern, prepackaged identification systems are used. They also provide the speed needed to make the examination a worthwhile one.

- A milk sample is considered contaminated when more than three species of bacteria are isolated. A quarter is considered to be infected when the same bacteria is isolated in at least two out of three milk samples. A quarter is considered to be cured when bacteria, isolated at drying off, are not present in any samples 28 days after calving. An uninfected quarter at drying off that is infected at calving is considered to indicate a new intramammary infection. A quarter that is infected at drying off but infected with another bacteria at calving also indicates a new intramammary infection.

- Selective culture plates, such as **biplates** (MacConkey agar and blood agar with 1% esculin), **triplates** (MacConkey agar, blood agar and TKT agar (thallium, crystal violet and staphylococcal toxin in 5%
blood agar with 1% esculin), Petrifilm® plates, which are selective culture media products. The MASTIK® diagnostic kit or the ColiMast® test can be used to differentiate between Gram-positive and Gram-negative pathogens and no growth, and may aid in the rational and targeted use of antimicrobial agents for clinical cases of mastitis. A commercially available cowside test for endotoxin (Limbast-test®) is available in Scandinavia. The test takes 15 minutes to run on milk samples and is able to detect the presence of endotoxin using the Limulus amebocyte lysate assay. The test therefore can detect the presence or absence of Gram-negative bacteria but does not differentiate between E. coli and K. pneumoniae. At least 10^4-10^5 cfu of Gram-negative bacteria are necessary for a positive test result; this does not decrease the clinical utility of the test, because low bacterial counts in the milk from infected quarters usually indicates that antimicrobial agents are not required in order to clear the infection.

There is interest in developing other cowside tests to determine whether the causative pathogen is Gram-negative or Gram-positive. One such approach uses dilution of the milk sample, filtration through a membrane with a pore size that retains bacteria, and staining of the bacteria with specific stains. The filtration procedure reportedly takes 5 minutes, but the need for microscopic examination decreases the utility of this as a cowside test.

A common diagnostic problem is a bacteriologically negative culture in cows with clinical mastitis. Even when milk samples are collected appropriately and bacteriological culture is done using routine laboratory methods, 15-40% of samples from clinical mastitis episodes are bacteriologically negative (yield no growth). Failure of these samples to yield a mastitis pathogen may be the result of spontaneous elimination of infection, a low concentration of pathogens in the milk, intermittent shedding of the pathogen, intracellular location of the pathogens or the presence of inhibitory substances in the milk. Augmented culture techniques may reduce, but do not eliminate negative culture results and may facilitate growth of contaminant organisms. Dairy producers and veterinarians therefore face a dilemma when no bacteria or bacteria commonly regarded to be of minor pathogenicity, such as C. bovis or coagulase-negative Staphylococcus spp., are cultured from the milk of cows with clinical mastitis, particularly if clinical signs persist. Most bacteriologically negative cases of clinical mastitis appear to be caused by low-grade infections with Gram-negative bacteria. When no bacterial pathogen can be isolated from cases of clinical mastitis using standard culture techniques, enzyme-linked immunosorbent assays (ELISAs) may be used to detect antigens against S. aureus, E. coli, S. dysgalactiae, and S. agalactiae. Antigens to these pathogens may be detectable using an ELISA in up to 50% of quarter samples from cows with clinical mastitis in which no pathogens were isolated but in which the SCC was more than 500 000 cells/mL. Despite these promising findings, ELISAs are not widely used in the identification of mastitis pathogens.

**Indirect tests for subclinical mastitis**

Indirect tests include SCCs using automated electronic counters, the California Mastitis Test, increases in electrical conductivity of milk, and increases in the activity of cell associated enzymes (such as NAGase) in milk. ELISA tests to detect neutrophil components have been developed but are not commercially available. Of these indirect tests, only the CMT and electrical conductivity can be used cowside, with CMT providing a more accurate screening test than electrical conductivity.

The somatic cell count of composite or quarter samples

There is a strong relationship between the SCC of quarter samples of milk and the milk yield, with SCC increasing slightly as milk production decreases but increasing markedly with intramammary infection of the quarter. The distribution of SCC in a herd therefore reflects the distribution of intramammary infections. The most important factor affecting SCC in an individual cow is the number of quarters infected with a major or minor pathogen. In most herds, the prevalence of infection will increase through a lactation and will also increase with the age of the cow. Cell counts in the first few days of the lactation are often exceptionally high and unreliable as indicators of intramammary infection, and in uninfected cows the counts will remain very low. However, older cows may have higher counts because the prevalence of infection is higher with age and older cows are more likely to have had previous infections with residual lesions and leaking of somatic cells into the milk. There are also consistent and significant differences in actual SCC between cows, individual cows tending to maintain the same class of count throughout their lives. Cows that have consistently low SCC do not seem to be more susceptible to mastitis than others. Attempts to base a breeding program to reduce the prevalence of mastitis on the selection of cows with an innately low composite SCC have been discarded because of fluctuations in numbers within cows.

Healthy quarters have a SCC below 100 000 cells/mL, and this cutpoint should be used to indicate the absence or presence of intramammary infection on a gland basis. This cutpoint looks very solid for a gland, because many milk components differ from normal values whenever the SCC exceeds 100 000 cells/mL. Moreover, mean SCC counts for bacteriologically negative quarters, quarters infected with minor pathogens and quarters infected with major pathogens were 68 000, 130 000, and more than 350 000 cells/mL, respectively.

Because of the time and labor saved it is now customary to do automated electronic cell counts on composite milk samples that have already been collected for butterfat testing. Regular reports of individual cow SCCs are therefore widely available in herds that routinely test production parameters of their cattle. An exciting new development in mastitis control is the portable somatic cell counter, which was designed for on farm use, thereby providing targeted and immediate SCC information for quarter or composite milk samples. Using the composite sample technique does distort the SCC; for example, the dilution of high-SCC milk from a bad quarter by low-SCC milk from three normal quarters could mean that a cow with one infected quarter might not be detected. Composite SCCs of less than 200 000 cells/mL are considered to be below the limit indicative of inflammation, even though uninfected quarters have a SCC of less than 100 000 cells/mL. Factors that affect the composite milk SCC include the number of infected quarters infected, the kind of infection (S. agalactiae is a more potent stimulator of cellular reaction than S. aureus), the strictness with which milk from cows with clinical mastitis is kept out of the bulk tank, the age of the cows (older cows have higher counts), the stage of lactation (counts are highest in the first days after calving and toward the end of lactation) and the herd's average production, the cell count reducing as milk yield increases.

A SCC scoring system that divides the SCC of composite milk into 10 categories from 0-9, known as linear score, is becoming more widely used. The linear score is a base 2 logarithm of the SCC (in cells/mL), whereby linear score = log2(SCC/100,000) + 3. Likewise, to calculate SCC (in cells/mL) from the linear score (LS), the following formula is used: SCC = 100 000 x 2^LS - 3. A SCC of
100,000 cells/mL therefore converts to a score of 3. Each 1-unit increase (or decrease) in linear score is associated with a doubling (or halving) of the SCC. For example, score 2 is equivalent to a SCC of 50,000 cells/mL, and scores of 4 and 5 correspond to 200,000 and 400,000 cells/mL. Conversion of SCC to linear score values is performed as shown in Tables 15.3 and 15.4. The principal reason for using the linear score is to achieve properties that are required in order to use conventional statistical methods: mean equal to median, normal distribution and uniform variance amongst samples within lactation, amongst cows within herd or among daughters within sire.

The proportion of neutrophils in the SCC is very low (<11%) in healthy quarters but is markedly increased in quarters with intramammary infection (to >90%). Accordingly, the percentage of neutrophils in the SCC may provide a useful indication of intramammary infection, but is not currently performed:^{58}

Somatic cell counts can also be determined for colostrum, where they are useful in indicating the presence of intramammary infection (Table 15.2). The equivalent SCC for CMT scores of negative or trace are similar for colostrum and milk, but the SCC for CMT scores of 1, 2 and 3 are shown in Table 15.4. If the CMT is used to minimize the false negative rate (produce the highest sensitivity), then the test should be read as negative (CMT = negative) or positive (CMT = trace, 1, 2 or 3). If the CMT is used to minimize the false-positive rate (produce the highest specificity) for culling decisions, then the test should be read as negative (CMT = negative or trace) or positive (CMT = 1, 2 or 3).

CMT scores can also be determined for colostrum, where the score is useful in indicating the presence of intramammary infection (Table 15.2). The equivalent SCC for CMT scores of negative or trace are similar for colostrum and milk, but the SCC for CMT scores of 1, 2 and 3 are shown in Table 15.4. If the CMT is used to minimize the false negative rate (produce the highest sensitivity), then the test should be read as negative (CMT = negative) or positive (CMT = trace, 1, 2 or 3). If the CMT is used to minimize the false-positive rate (produce the highest specificity) for culling decisions, then the test should be read as negative (CMT = negative or trace) or positive (CMT = 1, 2 or 3).

CMT scores can also be determined for colostrum, where the score is useful in indicating the presence of intramammary infection (Table 15.2). The equivalent SCC for CMT scores of negative or trace are similar for colostrum and milk, but the SCC for CMT scores of 1, 2 and 3 are shown in Table 15.4. If the CMT is used to minimize the false negative rate (produce the highest sensitivity), then the test should be read as negative (CMT = negative) or positive (CMT = trace, 1, 2 or 3). If the CMT is used to minimize the false-positive rate (produce the highest specificity) for culling decisions, then the test should be read as negative (CMT = negative or trace) or positive (CMT = 1, 2 or 3).

CMT scores can also be determined for colostrum, where the score is useful in indicating the presence of intramammary infection (Table 15.2). The equivalent SCC for CMT scores of negative or trace are similar for colostrum and milk, but the SCC for CMT scores of 1, 2 and 3 are shown in Table 15.4. If the CMT is used to minimize the false negative rate (produce the highest sensitivity), then the test should be read as negative (CMT = negative) or positive (CMT = trace, 1, 2 or 3). If the CMT is used to minimize the false-positive rate (produce the highest specificity) for culling decisions, then the test should be read as negative (CMT = negative or trace) or positive (CMT = 1, 2 or 3).

CMT scores can also be determined for colostrum, where the score is useful in indicating the presence of intramammary infection (Table 15.2). The equivalent SCC for CMT scores of negative or trace are similar for colostrum and milk, but the SCC for CMT scores of 1, 2 and 3 are shown in Table 15.4. If the CMT is used to minimize the false negative rate (produce the highest sensitivity), then the test should be read as negative (CMT = negative) or positive (CMT = trace, 1, 2 or 3). If the CMT is used to minimize the false-positive rate (produce the highest specificity) for culling decisions, then the test should be read as negative (CMT = negative or trace) or positive (CMT = 1, 2 or 3).

CMT scores can also be determined for colostrum, where the score is useful in indicating the presence of intramammary infection (Table 15.2). The equivalent SCC for CMT scores of negative or trace are similar for colostrum and milk, but the SCC for CMT scores of 1, 2 and 3 are shown in Table 15.4. If the CMT is used to minimize the false negative rate (produce the highest sensitivity), then the test should be read as negative (CMT = negative) or positive (CMT = trace, 1, 2 or 3). If the CMT is used to minimize the false-positive rate (produce the highest specificity) for culling decisions, then the test should be read as negative (CMT = negative or trace) or positive (CMT = 1, 2 or 3).

CMT scores can also be determined for colostrum, where the score is useful in indicating the presence of intramammary infection (Table 15.2). The equivalent SCC for CMT scores of negative or trace are similar for colostrum and milk, but the SCC for CMT scores of 1, 2 and 3 are shown in Table 15.4. If the CMT is used to minimize the false negative rate (produce the highest sensitivity), then the test should be read as negative (CMT = negative) or positive (CMT = trace, 1, 2 or 3). If the CMT is used to minimize the false-positive rate (produce the highest specificity) for culling decisions, then the test should be read as negative (CMT = negative or trace) or positive (CMT = 1, 2 or 3).

CMT scores can also be determined for colostrum, where the score is useful in indicating the presence of intramammary infection (Table 15.2). The equivalent SCC for CMT scores of negative or trace are similar for colostrum and milk, but the SCC for CMT scores of 1, 2 and 3 are shown in Table 15.4. If the CMT is used to minimize the false negative rate (produce the highest sensitivity), then the test should be read as negative (CMT = negative) or positive (CMT = trace, 1, 2 or 3). If the CMT is used to minimize the false-positive rate (produce the highest specificity) for culling decisions, then the test should be read as negative (CMT = negative or trace) or positive (CMT = 1, 2 or 3).
NAGase activity. The NAGase test is reputed to be the most accurate of the indirect tests and as good as SCC in predicting the infected status of a quarter. The NAGase test uses a less sophisticated reading instrument than the average automatic cell counter. If all tests are available it is best to consider the NAGase test and SCC as complementary tests and carry out both of them. Milk NAGase levels are high at the beginning and the end of lactation, as with cell counts. The test has also been validated for use with goat milk.

Electrical conductivity tests of quarter samples
A test that has received a lot of attention because it can be used in robotic milking systems is based on the increase in concentration of sodium and chloride ions, and the consequent increase in electrical conductivity, in mastitic milk. The electrolyte changes in milk are the first to occur in mastitis and the test has attractions for this reason. A number of factors affect these characteristics, however, and to derive much benefit from the test it is necessary to examine all quarters and use differences between the quarters to indicate affected quarters. For greater accuracy all quarters need to be monitored each day. An experimental unit that takes all these factors into consideration has been fitted to a milking machine and, by a computer-prepared analysis, monitors variations in electrical conductivity in each quarter every day. Electrical conductivity is attractive as a test because it measures actual injury to the udder rather than the cow's response to the damage, as SCC and NAGase activity do. However, a meta-analysis indicated that using an absolute threshold for conductance did not provide a suitable screening test, as both sensitivity and specificity were unacceptably low. The use of differential conductivity (within cow quarter comparison) results in improvement in test sensitivity and specificity, and is currently the only recommended application of this indirect test.

The most commonly promoted method for measuring electrical conductivity is a hand-held device with a built-in cup into which milk is squirted (foremilk is preferred). Experimentally induced clinical mastitis due to S. aureus and S. iberus was detectable by changes in electrical conductivity of foremilk: 90% of cases were detectable when clots first appeared and 55% of cases were detectable up to two milkings prior to the appearance of clots. This suggests that clinical mastitis associated with these two major pathogens may be able to be detected earlier by electrical conductivity than by waiting for milkers to detect visible changes in the milk.

Comparison of indirect methods
The effects of subclinical intramammary infection on several parameters in foremilk from individual quarter milk samples have been compared. Somatic cell count, electrical conductivity, pH, NAGase activity and the concentrations of potassium, lactose and alpha-1-antitrypsin were measured from individual quarters. Somatic cell count, NAGase activity, electrical conductivity and concentrations of sodium, alpha-1-antitrypsin and lactose were all useful indirect indicators of infection. The SCC was better able to discriminate between infected and uninfected quarters and cows than were the electrical conductivity, pH and NAGase activity.

Hematology and serum biochemistry
In severe clinical mastitis there may be marked changes in the leukocyte count, packed cell volume and serum creatinine and urea nitrogen concentration because of the effects of severe infection and toxemia. In particular, clinical mastitis episodes associated with Gram-negative bacteria frequently cause a profound leukopenia, neutropenia, lymphopenia and monocytopenia as a result of the endotoxemia, as well as an increased packed cell volume. In contrast, the leukogram in cattle with clinical mastitis associated with Gram-positive bacteria is normal or mildly increased.

Ultrasoundography of the mammary gland
Two-dimensional ultrasonographic images of the gland cistern, parenchymal tissue and teat are easily obtained using a 5.75 or 8.5 MHz linear array transducer, and ultrasonography is becoming more widely used to guide treatment of teat and gland cistern abnormalities. However, there are few reports of the use of ultrasonography to diagnose or prognose clinical mastitis episodes, although this is likely to be a fruitful area for investigation.

The best two-dimensional images of the udder parenchyma are obtained by clipping the hair on the udder and applying a coupling gel. This minimizes air between the transducer face and skin. Imaging the normal adjacent quarter is very helpful in identifying abnormalities. Imaging should be performed in two planes, sagittal to the teat (and therefore perpendicular to the ground), and transverse to the teat (and therefore horizontal to the ground). The injection of sterile 0.9% NaCl through a teat cannula into the gland provides a practical contrast agent that can help further define the extent of any abnormalities. The superficial mammary lymph nodes can be ultrasoned using a 7.5 MHz linear transducer, with the lymph node being well demarcated from the surrounding tissues. Mean lymph node length was 7.4 cm (range 3.5–15.0 cm) and mean depth was 2.5 cm (range, 1.2–5.7 cm). Lymph node size increased with age but was not correlated with SCC.

Mastitis produces an increased heterogeneous echogenicity to the milk in the gland cistern, compared to an uninfected quarter. It is important to make this visual comparison without altering the contrast and brightness setting on the ultrasonographic unit.

Three-dimensional ultrasonography of the bovine mammary gland and teat has recently been evaluated and has many promising applications.

Biopsy of mammary tissue
A biopsy of mammary tissue can be used for histological and biochemical evaluation in research studies. The use of a rotating stainless steel cannula with a retractable blade at the cutting edge has been described for obtaining biopsy material from cows. Despite some postoperative bleeding, milk yield and composition in the biopsied gland were affected only transiently.

NECROPSY FINDINGS
Necropsy findings are not of major interest in the diagnosis of mastitis and are

omitted here but included in the description of specific infections.

**DIFFERENTIAL DIAGNOSIS**

The diagnosis of clinical mastitis is not difficult if a careful clinical examination of the udder is carried out as part of the complete examination of a cow with systemic clinical findings. Examination of the udder is sometimes omitted in a recumbent animal only for severe mastitis to be discovered later. The diagnosis of mastitis depends largely upon the detection of clinical abnormalities of the udder and gross abnormalities of the milk or the use of an indirect test like the CMT to detect subclinical mastitis.

Other mammary abnormalities that must be differentiated from clinical mastitis include periparturient edema, rupture of the suspensory ligament, and hematoma. There are not accompanied by abnormalities of the milk unless there is hemorrhage into the udder. The presence of stray voltage in the milking plant should not be overlooked in herds where the sudden lowering of production arouses an unfounded suspicion of mastitis.

Differentiation of the different causes of mastitis is difficult on the basis of clinical findings alone but must be attempted, especially in peracute cases where specific treatment must be given before results of laboratory examinations are available. A pretreatment sample of milk from the affected glands for culture and antimicrobial sensitivity may provide useful information about the health record of the cow and the need to consider alternative therapies, and could provide information on new infections in the herd.

**TREATMENT**

The treatment of the different causes of clinical and subclinical mastitis may require specific protocols, which are described under specific mastitis pathogens later in the chapter. The general principles of mastitis treatment are outlined here.

**Historical aspects of antimicrobial therapy for clinical and subclinical mastitis**

Between about 1950 and 1990, on a worldwide basis, all forms of both clinical and subclinical bovine mastitis were treated with a wide variety of antimicrobial agents either by intramammary infusions or parenterally, and commonly by both routes in acute and peracute cases. Most veterinarians treated clinical mastitis and evaluated the response on the basis of the clinical outcome. In general, it was believed that antimicrobial agents were effective for the treatment of clinical and subclinical mastitis in lactating cows. However, there are very few scientific publications based on randomized clinical trials in which the efficacy of intramammary antimicrobial agents for treatment of clinical mastitis was compared to untreated controls. If antimicrobial agents were used and the animal recovered, it was assumed that treatment was efficacious. If the cow did not respond favorably, several reasons were usually enumerated for the treatment failure. However, most of these reasons, while biologically attractive, are hypothetical and have not been substantiated scientifically. Gradually, over the years, veterinarians began to doubt the efficacy of antimicrobial agents for the treatment of all cases of clinical mastitis. In addition, and of major importance, milk from treated cows had to be discarded for up to several days after the last day of treatment because of antimicrobial residues; this was a major expense. Currently, optimized treatment strategies focus on efficacy, economics, animal welfare aspects and the milk withheld time of antimicrobial treatment.

Efficacy is assessed on the basis of **clinical cure** or **bacteriological cure**. Most producers are interested in the return to normal milk (clinical cure) and are much less interested in the return to a sterile quarter (bacteriological cure). Because clinical mastitis is defined as abnormal milk, the return to normal (‘drinkable’) milk represents a clinical cure. Bacteriological cure represents the inability to isolate the initial pathogen 14–28 days after the start of treatment. Other important indicators of efficacy are milk production, dry matter intake, the amount of saleable milk and mortality or culling rates after treatment.

Some examples of the efficacy or ineffectiveness of antimicrobial agents illustrate the controversy. It is well accepted that the cure rate following intramammary treatment of clinical or subclinical mastitis due to *S. agalactiae* in the lactating cow is high (80–90%). In contrast, the cure rate of clinical and subclinical mastitis due to *S. aureus* in the lactating cow is considerably lower (40–50%), but certainly not 0%. In herds with a low prevalence of contagious mastitis, most cases of mild clinical mastitis (abnormal secretion only) in lactating cows are due to environmental streptococci and coliforms and may recover without antimicrobial therapy, although antimicrobial administration increases the clinical and bacteriological cure rate. Antibacterial antimicrobial agents may be ineffective for the treatment of clinical mastitis associated with *M. bovis, A. pyogenes, Nocardia spp.*, and *P. aeruginosa*.

In the 1970s dairy processing plants, veterinarians, consumer advocates, public health authorities and milk-quality regulating agencies began to express concern about antimicrobial residues in milk from cows treated for mastitis. The public health and milk industry concerns about residues combined with the controversy about the efficacy of antimicrobial agents for clinical mastitis has also provided a stimulus to evaluate the efficacy and consequences of using antimicrobial agents.

Between about 1950 and 1990, much emphasis has been placed on alternative methods of treating clinical mastitis, leading to a reduction in the use of antimicrobial agents during the lactating period. Such strategies have been defended based on the lack of information concerning the efficacy and economics of antimicrobial therapy associated with pathogens other than *S. agalactiae*, and by the need to reduce the risk of residue violation. However, a recent study concluded that not administering antibiotics to cows with clinical mastitis was imprudent and unethical.

There is a need for randomized controlled field trials to evaluate the use of antimicrobial agents for the treatment of clinical mastitis, the design for such trials and the statistical analysis required have been reviewed. Well conducted clinical mastitis treatment trials represent an invaluable, although difficult and expensive, effort to evaluate efficacy of antimicrobial agents under field conditions. The use of intramammary antimicrobial agents for the treatment of clinical mastitis in lactating cows in 40 dairy herds over 4 years found an economic benefit compared to nonmedicated controls. In the antimicrobial-treated group, the number of pathogens in the milk following treatment was reduced, the number of quarters returning to normal milk was increased, and the number of cured quarters was increased. In order to use antimicrobial agents for the treatment of subclinical mastitis at the end of lactation, known as dry cow therapy, is accepted worldwide and is based on scientific evidence using randomized clinical trials. Dry cow therapy is one of the principles applied in the effective control of bovine mastitis, in which much progress has been made since the early 1970s.

**Treatment strategies**

The treatment strategy will depend on whether the mastitis is clinical or subclinical, and the health status of the herd, including its mastitis history. Clinical mastitis is further categorized as abnormal milk, abnormal gland or abnormal cow, as described under Diagnosis. If treatment is indicated, the major decision is whether to administer antimicrobial agents parenterally or by intramammary infusion.

An important aspect of treatment is the accurate positive identification of the animal(s) to be treated, the recording of the relevant clinical and laboratory information, and the treatments being used.

- Clinical mastitis
- Subclinical mastitis
- Antimicrobial treatment
- Lameness
- Dry cow therapy
- Milk processing
- Animal welfare
Options for treating cows with clinical mastitis include treating all cows with antimicrobial agents, treating none of the cows with antimicrobial agents or treating only specific cows with antimicrobial agents. Treating all cows results in increased costs for those cows with clinical mastitis associated with pathogens not susceptible to the antimicrobial agent used, especially if the signs are likely to resolve before the milk withholding period has expired. Treatment of all cows is also associated with increased risk of violative residues in the bulk milk. Treating none of the cows with antimicrobial agents has animal welfare implications, in that an effective treatment is not administered to some cattle with clinical mastitis, and non-treatment allows Gram-positive pathogens to persist, increasing the probability of a recurrence of clinical mastitis or causing a herd epidemic of mastitis. Accordingly, non-treatment of all cases of mastitis is not a viable option. Treating only specific cows with antimicrobial agents requires an accurate method of determining which animals should be treated. However, clinical judgment and predictive models are too inaccurate to distinguish between clinical mastitis associated with Gram-negative and Gram-positive pathogens. To select cows for antimicrobial therapy on the basis of bacteriological culture is costly and delays treatment; clinical judgment would still be necessary because bacteria are not isolated from 15-40% of milk samples from cows with clinical mastitis.

Veterinarians should always ask and answer four questions related to antimicrobial therapy in bovine mastitis:

- Is antimicrobial therapy indicated?
- Which route of administration (intramammary, parenteral or both) should be used?
- Which antimicrobial agent should be administered?
- What should be the frequency and duration of treatment?

Is antimicrobial therapy indicated?
The first decision is whether to treat a particular case with antimicrobial agents and whether supportive therapy is required. Therapy decisions should be made in context with the overall objectives of the lactating cow treatment protocol. The availability of approved, effective treatment products is an essential component of the program. A number of factors are important in determining which cases of mastitis should be treated during lactation. These factors include the type of pathogen involved, the type and severity of the inflammatory response, the duration of infection, the stage of lactation, and the age and pregnancy status of the cow.

Type of pathogen involved
There are marked differences in the bacteriological cure rates of the various major mastitis pathogens after therapy during lactation. The outcome of treatment during lactation is poor for cases of S. aureus. On the other hand, S. agalactiae responds extremely well to lactating cow therapy and all infected cows should be treated. Cases of mastitis associated with environmental organisms have reasonable, but variable, cure rates.

Type and severity of the inflammatory response
The predominant type of inflammatory process involved influences the objectives of the therapy program. Herds with clinical mastitis problems will aim at reducing clinical signs, returning the milk to saleable quality and avoiding residue violations. Herds with a predominance of subclinical mastitis are concerned with avoiding the spread of infection and reducing the prevalence of the major pathogens involved. Both types of herd have the primary objective of restoring the production potential.

The severity of the inflammatory response is also important in the selection of cases for mastitis therapy during lactation. Heat, pain and swelling of the quarter (abnormal gland) are clinical signs that indicate the need for antimicrobial therapy. Many producers, however, will treat any cow that shows clots in the milk (abnormal milk). There are no reports to verify that treatment of cows exhibiting abnormal milk only is efficacious and economically justifiable, although it is probable that treatment of clinical mastitis episodes of abnormal milk but normal gland due to S. agalactiae is efficacious and economic. Treatment success is lower in cows with high NAGase concentrations in milk compared to low NAGase concentrations.

Duration of infection
For the contagious organisms, especially S. aureus, the duration of infection is an important determinant of its susceptibility to therapy during lactation. In chronic S. aureus mastitis, the organism survives intracellularly in leukocytes, becomes walled-off in small abscesses of mammary ducts, and has the ability to exist in the L-form state. At this point S. aureus is virtually incurable during lactation. With new methods of automated detection of subclinical intramammary infection such as in-line electrical conductivity measurement, new infections may be detected much earlier. The cure rate of S. aureus during lactation needs to be re-evaluated when treatment is administered early in the course of infection.

Stage of lactation
The stage of lactation is an important determinant of the benefit-cost ratio of mastitis therapy during lactation. It may be uneconomical to treat even cases with a high probability of cure during late lactation.

Age and pregnancy status of cow
The probability of a cure is greater in young cows, and age should be considered in selecting cases for mastitis therapy during lactation. The economic aspects of treatment for late-lactation, non-pregnant cows are obviously different from those for midlactation pregnant cows.

A mastitis therapy program for lactating cows should be based on a complete understanding of the mastitis status of the herd, and individual cow treatment decisions should be consistent with the overall herd mastitis therapy program. A record system for treatment should be established so that it is possible to monitor the efficacy of the mastitis treatment program.

The udder health status in a particular herd will determine whether the lactating cow mastitis therapy strategy should be targeted at the individual cow level or at the herd level. The level of emphasis should clearly reflect the objectives of the therapy program. For example, a herd with low bulk tank milk SCC and sporadic cases of environmental mastitis should target the lactating cow therapy strategy at the cow level. The primary objectives would be to alleviate clinical signs, to achieve a bacteriological cure and to restore the cow's production. On the other hand, a herd with moderate to high bulk tank milk SCCs and a significant prevalence of contagious organisms should aim the program at the herd level. In this case, the objective would be to limit the spread of infection, markedly reduce or eradicate a specific pathogen and increase herd production. A clear statement of treatment philosophy (individual cow level or herd level) in a particular
clinical or subclinical mastitis does not influence the cure rate achieved with treatment. These factors can significantly influence the cure rate achieved with therapy, or the economic benefit realized. The herd history of udder health will indicate the probable cause of clinical mastitis. Cows with mild cases of clinical mastitis (abnormal milk only) in herds with a low prevalence of contagious mastitis pathogens are likely to be affected with environmental pathogens and commonly return to clinically normal milk in four to six milking. This has led to the development of treatment algorithms based on the results of culturing clinical cases using selective media. Using this approach, milk cultures are obtained from all cattle with clinical mastitis and plated using biplates or triplicates. All cattle with abnormal glands or signs of systemic illness (abnormal cow) are currently treated with antimicrobial agents and appropriate ancillary treatment, with subsequent antimicrobial treatment based on the preliminary culture results at 18–24 hours or the final culture results at 48 hours. In contrast, treatment is initially withheld from all cattle demonstrating abnormal secretion only; antimicrobial treatment is instituted based on the culture results. One such scheme recommends using intramammary antibiotics to treat affected quarters with *S. aureus*, coagulase-negative staphylococci and environmental streptococci, infusing intramammary antibiotics into all quarters of cows with one or more quarters infected with *S. agalactiae* and not administering antibiotics to cows with coliform bacteria or no growth. When using this delayed approach to antimicrobial treatment, it is important that cattle with abnormal milk only are closely monitored and that antimicrobial treatment is immediately instituted when signs of an abnormal gland or abnormal cow are present. The major difficulty with implementing the delayed approach is the difficulty in trans-

- Milk and epithelial lining of the ducts and alveoli
- Parenchyma of the mammary gland

The cow (Table 15.5).

In general, infections confined primarily to the milk and ducts (such as *C. bovis*, coagulase-negative staphylococci) are easily treated with intramammary antibiotics. In contrast, infections due to mastitis pathogens with potential for systemic infection (such as *E. coli*, *K. pneumoniae*, *M. bovis*) are best treated with parenteral antibiotics. Mastitis pathogens that are the most difficult to treat are those that are principally infections of parenchymal tissue (such as *S. aureus*, *A. pyogenes*); it is because it is more difficult to attain and maintain an effective antibiotic concentration at this anatomical site when administering antibiotics by the intramammary or parenteral routes.

Which antimicrobial agent should be administered?

The third decision is the antimicrobial agent. The selection of the antimicrobial class for the particular mastitis pathogen has traditionally been based on culture and susceptibility testing and, although some in vivo data are available, the choice is still largely dependent on case studies rather than on controlled experiments. Culture and antimicrobial susceptibility testing of the pathogen is not necessarily a justifiable basis for selecting the antimicrobial agent to be used in individual cows, and the response to treatment of clinical mastitis in two recent studies was unrelated to the results of in vitro susceptibility tests. Antimicrobial agents are usually selected based on availability of labeled drugs, clinical signs in the cow, milk culture results for previous mastitis episodes in the herd, experience of treatment outcome in the herd, treatment cost and withdrawal times for milk and slaughter. Many veterinarians and researchers have also recommended the use of susceptibility testing to guide treatment decisions. The validity of agar diffusion susceptibility breakpoints derived from humans in the treatment of bovine mastitis has not been established and is extremely questionable because bovine mastitic milk pH, electrolyte, fat, protein and neutrophil concentrations, sensitivity and effectiveness of drug concentrations and pharmacokinetic profiles differ markedly from those of human plasma. Moreover, antibiotics are distributed unevenly in an inflamed gland, and high antibiotic concentrations can alter neutrophil function in vitro and therefore have the potential to inhibit bacterial clearance in vivo.

Adequate databases of in vitro minimum inhibitory concentration (MIC) breakpoints currently exist for many of the pathogens associated with mastitis; the clinical importance of many of these breakpoints is seen in Table 15.5. A detailed discussion of antimicrobial classes and their properties is provided in Chapter 14.
values for clinical mastitis pathogens are currently unavailable, although adequate databases are available for subclinical mastitis isolates. Although we have a good knowledge of the pharmacokinetics of many parenteral antibiotics used to treat clinical mastitis, most pharmacokinetic data have been obtained in healthy cattle and it has not been determined whether pharmacokinetic values in healthy cows are the same as those in cows with clinical mastitis. In addition, pharmacokinetic values for many of the intramammary antibiotics used to treat clinical mastitis are unknown, and we have a limited understanding of the pharmacodynamics of antibiotics in treating mastitis. More importantly, the breakpoints currently recommended for all parenteral and almost all intramammary administered antibiotics are based on achievable serum and interstitial fluid concentrations in humans after oral or intravenous antibiotic administration. The relevance of these breakpoints to achievable milk concentrations in lactating cows after intramammary, subcutaneous, intramuscular or intravenous administration is dubious at best.85

Results from field studies are available to evaluate the validity of susceptibility breakpoints in guiding treatment of cows with clinical or subclinical mastitis. The results from these field studies suggest that the following antibiotics may have valid (but not necessarily optimal) breakpoints for treating clinical or subclinical mastitis associated with specific bacteria: parenteral penicillin G for subclinical *S. aureus* infections, intramammary cephalorin for clinical *Streptococcus* spp. infections, and parenteral trimethoprim-sulfadiazine for clinical *E. coli* infections. Of these three antibiotics, the breakpoints for penicillin G and cephalorin have only been validated for bacteriological cure, whereas the breakpoint for trimethoprim-sulfadiazine is validated for clinical cure.84

Because duration of infection before treatment, antibiotic dosage, dosage interval and duration of treatment influence treatment outcome, many more field studies must be completed to validate the currently assigned antibiotic breakpoints for pathogens causing clinical mastitis.

To properly utilize the known pharmacokinetics of parenterally and intramammarily administered drugs, it is necessary to know something about their diffusion into mammary tissue, the degree of binding of a drug to mammary tissues and secretions, the ability to pass through the lipid phase of milk and the degree of ionization. All of these factors influence the level of the antibiotic in the mammary gland. For lactating cows the preferred treatment is one that maintains a MIC for 72 hours without the need for multiple infusions and without prolongation of the withdrawal time. The most successful antimicrobial agents for dry period treatment are those that persist longest in the udder, preferably as long as 8 weeks. These characteristics depend on the release time from the transport agent in the formulation, and the particle size and diffusion capabilities of the antibiotic.

The formulation of the preparation will affect the duration of the maintenance of the MIC. The third-generation cephalosporins (such as ceftiofur) and fluoroquinolones are the drugs of choice for use in cases in which the infection may be associated with either a Gram-positive or Gram-negative organism; however, these antimicrobial agents may not be able to be used to treat mastitis in many countries. Mixtures of penicillin and an amino-glycoside are also in common use for this purpose. Penicillin G and penethamate are favored for Gram-positive infections.

Of special importance are the beta-lactamase-producing strains of *S. aureus*, against which beta-lactam penicillins are ineffective; cloxacillin is a commonly used and effective intramammary formulation for these strains of *S. aureus*. The drugs that have the best record of diffusion through the udder after intramammary infusion are penethamate, ampicillin, amoxicillin, erythromycin and tylosin. Those of medium performance are penicillin G, cloxacillin and tetracyclines. Poor diffusers, which have a longer half-life in the udder because they bind to protein, include streptomycin and neomycin. Streptomycin is not much used now because of the high level of resistance to it, especially by *S. uberis* and *E. faecalis*.

What should be the frequency and duration of treatment?

The fourth decision is the frequency and duration of treatment. The frequency of administration for parenterally administered antimicrobial agents is dependent primarily on their pharmacokinetics and pharmacodynamics. Fluoroquinolones and aminoglycosides are concentration-dependent antimicrobial agents where increasing concentrations at the site of infection increase the bacterial kill rate. Macrolides, beta-lactams, and lincosamides are time-dependent antimicrobial agents where exceeding the minimum inhibitory concentration at the site of infection for a prolonged percentage of the interdosing interval correlates with improved efficacy.85

In contrast, the frequency of administration for intramammary formulations is dependent primarily on the milking schedule, in that these agents are primarily cleared by milk removal. For example, the clearance of pirlimycin is strongly and positively correlated (r = 0.97) to 24-hour milk production at the time of dosing.88 With all intramammary formulations being licensed based on the results of studies of twice-daily milking, the recent industry trend in some parts of the world towards thrice-daily milking has created uncertainty as to whether intramammary treatment should be repeated after every milking, or even whether once-a-day intramammary administration is as efficacious as twice- or thrice-daily administration.

Recent studies have confirmed long held beliefs that appropriate antimicrobial therapy (commonly called extended or aggressive antimicrobial therapy) for 5–8 days is much more effective in treating intramammary infections than label intramammary therapy (2–3 d). In other words, increasing the duration of antimicrobial administration increases treatment efficacy.89–92

Extended antimicrobial therapy is opposed by producers because such treatment may be off-label and results in a longer milk withhold time, and consequently the amount of milk that has to be discarded. Extended therapy is opposed by dairying administrators because of the inevitable increase in the number of infringements of health regulations relating to antibiotic residues in milk. The inappropriately short treatment duration for most intramammary products has been a major hindrance to developing effective antimicrobial treatment protocols.

**Intramammary antimicrobial therapy**

For reasons of convenience and efficiency, antimicrobial udder infusions are in common use for the treatment of certain causes of mastitis in lactating cows, and for dry cow therapy. For example, the cure rate of *S. agalactiae* using intramammary infusions in lactating cows exceeds 95%. Disposable tubes containing suitable antimicrobials in a water-soluble ointment base are ideal for dispensing and for the treatment of individual cows. Multipledose bottles containing aqueous infusions are adequate, and much cheaper per dose when large numbers of quarters are to be treated, but repeated use of the same container increases the risk of contamination. The degree of diffusion into glandular tissue is the same when either water or ointment is used as a vehicle for infusion; the duration of retention within the gland depends on the vehicle.

Most antimicrobial agents currently available in the USA in commercial intramammary infusion products are active against the staphylococci and streptococci,93 with cephalorin (a first-generation cephalosporin) having good
activity against coliform bacteria, and ceftiofur (a third-generation cephalosporin) having excellent activity against coliform bacteria. Until recent years the emphasis was on the elimination of Gram-positive cocci from the udder, but Gram-negative infections, especially E. coli, have increased in prevalence to the point where a broad-spectrum preparation is almost essential for both lactation and dry period treatments.

The choice of antimicrobial agents for intramammary infusion should be based on:

- Spectrum of bacteria controlled
- Diffusibility through mammary tissue
- Cost

Strict hygiene is necessary during treatment to avoid the introduction of bacteria, yeasts and fungi into the treated quarters; the use of a short cannula that just penetrates the external sphincter is preferred as it is less likely to introduce bacteria and leaves more of the keratin plug in place in the streak canal; the keratin plug has antimicrobial properties itself. Care must be taken to insure that bulk containers of mastitis infusions are not contaminated by frequent withdrawals and that individual, sterilized teat cannulas, usually part of commercial, single-dose ointment tubes, are used for each quarter. Bulk treatments are best avoided because of the high risk of spread of pathogens.

Infusion procedure

The teats must be cleaned and sanitized before infusing the quarter in order to avoid introduction of infection. The following steps are recommended:

- Clean and dry the teats
- Dip teats in an effective germicidal product. Allow 30 seconds contact time before wiping teats with an individual disposable towel (one towel/cow, use one corner of the towel for each teat)
- Thoroughly clean and disinfect each teat end with cotton soaked in 70% alcohol. Use a separate piece of cotton for each teat
- Prepare teats on the far side of the udder first, followed by teats on the near side
- Treat quarters in reverse order; near side first, far side last
- Insert only the tip of the cannula into the teat end (partial insertion). Do not allow the sterile cannula to touch anything prior to infusion. Most approved dry cow infusion products (and lactating tubes, too) are marketed with a dual cover that can be used for partial or full insertion
- Dip teats in a germicidal product after treatment
- Identify treated cows and remove from the milking herd to prevent antimicrobials from entering the milk supply.

Diffusion of infused intramammary drugs is often impeded by the blockage of lactiferous ducts and alveoli with inflammatory debris. Complete emptying of the quarter by the parenteral injection of oxytetracycline (10–20 IU intramuscularly) followed by hand-stripping of affected quarters before infusion has been recommended in cases of clinical mastitis, but efficacy studies are lacking, the volume stripped is usually small and the procedure is painful to the cow. If stripping is performed, the intramammary infusion is given after the last stripping of the day has been done, avoiding any further milking of the gland until the next milking. Our current knowledge can be summarized by the following: 'To strip or not to strip, that is the question.'

Parenteral antimicrobial therapy

This should be considered in all cases of mastitis in which there is an abnormal gland or abnormal cow (fever, decreased appetite, or inappetence). The systemic reaction can usually be brought under control by standard doses of antimicrobial agents but a bacteriological cure of the affected glands is seldom achieved because of the relatively poor diffusion of the antimicrobial from the blood into the milk. However, the rate of diffusion is greater in infected than in normal quarters. Parenteral treatment is also recommended when the gland is markedly swollen and intramammary infusions are unlikely to diffuse to all parts of the glandular tissue. To achieve adequate therapeutic levels of an antimicrobial in the mammary gland by parenteral treatment it is necessary, for the above reasons, to use higher than normal dose rates daily for 3–5 days. Milk from treated cows must be withheld from the bulk tank for the stated period of time of that antimicrobial following the date of last treatment.

Treatment of lactating quarters

There are three situations to consider: the emergency single case of clinical mastitis requiring immediate treatment, the herd with a problem of too many clinical cases or intractable cases, but where the identity of the pathogen is known, and the cow with subclinical mastitis.

Emergency treatment when the type of infection is unknown

Cases of acute and peracute mastitis (abnormal cow) in lactating cows, and in dry cows close to calving, are serious problems for the field veterinarian. The need for treatment is urgent; it is not possible to wait for the results of laboratory tests to guide the selection of the most appropriate antibiotic. Clinical findings, season of the year and management practices may give a broad hint as to the specific bacterial cause, but in most such circumstances it is necessary to use a broad-spectrum approach to treatment. Parenteral therapy with oxytetracycline (administered intravenously to increase bioavailability and therefore plasma and milk concentrations), a potentiated sulfonamide or similar broad-spectrum antimicrobial agent should be supplemented with intramammary infusion with a beta-lactamase-resistant antimicrobial such as a first-generation cephalosporin (ceftiofur), a third-generation cephalosporin (e.g. ceftiofur), penicillin G-neomycin combination or other approved broad-spectrum intramammary infusion. Parenteral ceftiofur is not effective in clinical mastitis episodes that have abnormal secretion or abnormal gland and secretion.

Field studies show that, in herds in which clinical mastitis is often caused by environmental pathogens, intravenous administration of oxytetracycline, intramammary infusion of ceftiofur and supportive therapy (including intravenous administration of flunixin meglumine or fluids) produces a higher rate of clinical and bacteriologic cure than supportive treatment alone. In addition, antimicrobial treatment is more effective than supportive treatment alone. In cows with clinical mastitis caused by E. coli the use of procaine penicillin G IM was no more effective than not using antimicrobial agents; this result is expected based on penicillin's Gram-positive spectrum of activity. Knowledge of the likely causative agent is therefore helpful when making decisions about therapy of clinical mastitis episodes during lactation.

Provision of other supportive therapy such as fluids and electrolytes is also crucial to the survival of the cow and minimization of the severity of the mastitis and extent of permanent injury to the udder. The efficacy of frequent stripping, with or without intramammary infusion, is uncertain. NSAIDs decrease pain associated with an abnormal gland; in addition, they enhance recovery and reduce fever in severe cases.

Treatment when the infecting organism is known

A common situation encountered by a bovine practitioner is the dairy herd that has had an outbreak of clinical mastitis or has received a warning notice from the milk processor that the bulk milk SCC or bacterial count is above acceptable limits. The situation calls for a complete mastitis control program, including conducting an
investigation to determine the causative bacteria present, the source of the infection, hygiene in the milking parlor and the importance of risk factors such as milking machine management, plus recommended antimicrobial preparations selected on the basis of the causative agent. Treatment of a number of identified subclinical cases at the commencement of the program, and of individual cases subsequently, can be based on the known common infection in the herd. Among Gram-positive cocci, the response to antimicrobial agents is excellent for streptococci. For staphylococci a cure rate of 65% is about the best that can be expected, and unless there are good reasons for doing otherwise it is recommended that treatment be postponed until the cow is dry. Standard treatments for lactating cows include penicillin alone (100,000 units) or in combination with streptomycin (1 g) or neomycin (500 mg), and a combination of ampicillin (75 mg) and sodium cloxacin (200 mg). Acid-resistant penicillins, e.g. phenoxymethylpenicillin, are probably not best used as mammary infusions because of their ability to pass through the human stomach, thus presenting a more serious potential threat to humans drinking contaminated milk. Because of the widespread and often indiscriminate use of penicillin, a large part of the mastitis that occurs is associated with penicillin-resistant bacteria, especially S. aureus. Treatment programs need to take this into account when recommendations are made about the antibiotic to be used.

Intramammary infections associated with environmental streptococci that manifest signs of clinical mastitis are usually acute but only moderately severe. In most of these cases the streptococci are sensitive to antimicrobial agents, and they often recover spontaneously with good management and nursing care. If not, they usually respond well to therapy. Bacteriological cure rates of 60–65% can be expected following a single intramammary infusion of a cephalosporin product. In one randomized controlled field trial of clinical mastitis associated with Streptococcus spp. or coliform bacteria, the clinical cure rate by the tenth milking was significantly higher when intramammary cepharpin, intravenous oxytetracycline, or both, were used along with supportive therapy (oxytocin and stripping of affected glands and, in severely affected cows, the use of flunixin meglumine and fluids) compared to supportive treatment alone.99 These results indicate that, in herds in which clinical mastitis is often associated with environmental pathogens, antimicrobial therapy and supportive therapy may result in a better outcome than supportive therapy alone.

Treatment of subclinical mastitis
It is generally considered not advisable to treat subclinical mastitis during lactation. However, it is important to consider the causative organism and the udder health status of the herd. There are several situations in which lactational therapy of subclinical mastitis is indicated; for example, herds with S. agalactiae infections should consider several approaches to therapy during lactation. S. agalactiae infections respond well to therapy during lactation, with cure rates of 80–100% expected.90 All approved intramammary therapy preparations are efficacious, including penicillin, cephalosporins, cloxacillin and erythromycin. In herds with a high prevalence of S. agalactiae mastitis, blitz therapy can be used for eradication of the pathogen, increased milk production and reduced penalties for high SCCs. There is, however, a risk of residue violation, problems with disposal of milk from treated cows and considerable costs involved. It is also important to insure that standard mastitis control procedures, such as postmilking teat disinfection and blanket dry cow therapy, have been implemented. The benefit:cost ratios for various approaches to blitz therapy of S. agalactiae infected herds have been studied.91 The prevalence of infected cows, and their stage of lactation, are important determinants of the type of program selected.

Therapy of cows with subclinical mastitis due to S. aureus during lactation is much less rewarding. Under field conditions, cases of S. aureus are difficult to cure during lactation. Reported cure rates following intramammary therapy are between 15% and 60%. Lactational therapy of subclinical S. aureus mastitis using intramuscular penicillin along with intramammary amoxicillin infusion, compared with the intramammary infusion alone, increased the cure rate to 40%, which represented a doubling of the cure rate with intramammary therapy alone.46 If treatment by this method is used in combination with data on the age of cow, stage of lactation, duration of infection and level of SCC, the economic benefit of treating some cases of S. aureus mastitis during lactation may be attractive. Subclinical infections associated with environmental streptococci, and occasionally by coliform organisms, can be found in moderate numbers in some herds.90 Although spontaneous cure rates are higher with these environmental infections, individual cows may merit treatment during lactation. In these cases, the previously listed factors should be used, and are important in the selection of cases to be treated.

Prepartum antibiotic treatment of heifers is of benefit in herds experiencing a high incidence of clinical mastitis in recently calved heifers. Coagulase-negative staphylococci are frequently isolated from late-gestation heifers, and intramammary treatment with sodium cloxacin (200 mg) or cepahpin sodium (200 mg) 7 days before expected parturition is highly effective and economically beneficial.90

Anti-inflammatory agents
NSAIDs have been evaluated for the treatment of field and experimental cases of acute and peracute mastitis. NSAIDs have beneficial effects on decreasing the severity of clinical signs based on changes in rectal temperature, heart rate, rumen motility and pain associated with the mastitis, and are routinely administered as part of the initial treatment of cattle with severe clinical mastitis and marked systemic signs. On the basis of one comparative study, NSAIDs appear to ameliorate systemic abnormalities to a greater degree than corticosteroids.101 The strongest evidence available to support the administration of NSAIDs is available for ketoprofen and phenylbutazone.

Ketoprofen at 2 g intramuscularly once daily combined with sulfadiazine and trimethoprim intramuscularly given daily to cows with acute clinical mastitis, and complete milking of affected quarters several times daily, significantly improved survival and milk production compared to cows not receiving the NSAID.102 A reanalysis of the published results indicated that phenylbutazone at 4 g intramuscularly once daily combined with sulfadiazine and trimethoprim intramuscularly given daily to cows with acute clinical mastitis significantly improved the percentage of cows with milk production returning to more than 75% of previous levels compared to cows not receiving the NSAID.103 However, intramuscular administration of phenylbutazone is not currently recommended because of the potential for myonecrosis. Dipyrene at 20 g intramuscularly once daily in the same study was not effective.103

There is no evidence that treatment of clinical cases with NSAIDs alters the inflammatory response in the udder, although pretreatment of cattle with experimentally induced mastitis does alter the local (glandular) inflammatory response to infection. Flunixin meglumine concentrations are low in milk, which is consistent with its properties as a weak acid, which has difficulty crossing the blood–milk barrier.104 Flunixin meglumine (2 mg/kg, intravenously, twice 24 h apart) did not alter the survival rate of dairy cows with severe E. coli or S. uberis mastitis compared to intravenous administration of 45 L of isotonic crystallloid fluids.105 The one-time administration of
response obtained depends particularly on the causative agent, the speed with which treatment is commenced, and other factors described above. A ‘cure’ may mean disappearance of clinical signs, elimination of the infectious cause, or both of those plus return to normal function and productivity. Which of these is the objective in any particular case or herd will influence the decisions to be made about treatment in an individual case of the disease.

Failure to respond to therapy of the lactating cow may be due to:

- The presence of microabscesses and inaccessibility of the drug to the pathogen
- Ineffective drug diffusion
- Inactivation of the antimicrobial by milk and tissue proteins
- Inefficient killing of the bacteria and intracellular survival of bacteria
- Increased antimicrobial resistance
- The development of L-forms of bacteria.

Dry cow therapy

Dry cow therapy is the use of intramammary antimicrobial therapy immediately after the last milking of lactation and is an important component of an effective mastitis control program. Intramammary infusions at drying off decrease the number of existing infections and prevent new infections during the early weeks of the dry period. Dry cow therapy should be routinely administered and remains one of the cornerstones of an effective mastitis control program.

Blanket dry cow therapy is treatment of all four quarters at drying off, compared to selective dry cow therapy based on treatment of only those quarters that are infected. When subclinical mastitis is very low in some herds, selective dry cow therapy can be considered, but nearly all herds use blanket dry cow therapy.

The problem with selective dry cow therapy is the accuracy of available indirect tests to ‘select’ cows for treatment or non-treatment. Currently available indirect tests are not sufficiently accurate (the exception being quarter milk cultures) to be used as a basis for selective dry cow therapy.

Intramammary infusions approved for dry cow therapy contain high levels of antimicrobial agents in a slow-release base that maintains therapeutic levels in the dry udder for long periods of time. Most dry cow therapy infusion products are intended to eliminate existing infections due to *S. aureus* and *S. agalactiae* at drying off and to prevent new infections due to the same pathogens and environmental streptococci in the early dry period.

In herds with a high prevalence of contagious mastitis, dry cow therapy has been efficacious and economically beneficial in reducing the prevalence of intramammary infections. The consistent application of effective mastitis control procedures has reduced the prevalence of contagious pathogens and the bulk tank milk SCC (<300,000 cells/mL) and owners of these herds questioned dry cow therapy because of the economics and the concerns of residues in the milk. Field trials in herds with a low prevalence of contagious mastitis indicate that dry cow therapy at the end of lactation increased 17-week milk production during the subsequent lactation and was economically beneficial compared to not treating them. However, in the subsequent lactation, the incidence of clinical mastitis was not reduced nor were the SCCs significantly different from those of cows not treated at the end of lactation.

The most effective time to treat subclinical intramammary infections is at drying off. Dry cow therapy has the following advantages over lactation therapy:

- The cure rate is higher than that achieved by treatment during lactation
- A much higher dose of antimicrobial can be used safely
- Retention time of the antimicrobial in the udder is longer
- The incidence of new infections during the dry period is reduced
- Tissue damage by mastitis may be regenerable after parturition
- Clinical mastitis at calving may be reduced
- The risk of contaminating milk with antimicrobial residue is reduced.

Selection of a suitable dry period therapy should take into account the fact that Gram-negative infections are not common at that time because of the high concentration of lactoferrin in the dry secretions. Accordingly, attention should be directed at the inclusion of a potent antibiotic against *Streptococcus spp.*, beta-lactamase-producing *S. aureus*, and *P. pyogenes* Cloxacillin, nafcillin, and cephalosporins are popular for the purpose; for example, a recommended treatment is cephalin or sodium cloxacillin in a slow-release base with an expected cure rate of 80% against streptococci and 60% against *S. aureus*.

Most dry cow preparations maintain an adequate minimum concentration in the quarter for about 4 weeks, but some persist for 6 weeks. There is little, if any, value in treating cows again before the due calving date. There is always a possibility of introducing infection while infractions may offset the benefits of therapy and further increase the risk of antimicrobial resistance in the udder.

Preparation of heifers for lactation

Intramuscular or intravenous injections of antibiotics (over 90% of cases) are used to treat subclinical intramammary infections of heifers. This is usually followed by immediate access to drinking water followed by immediate access to drinking water.

Supportive therapy

Supportive treatment, including the intravenous administration of large quantities of isotonic crystalloid fluids, is indicated in cattle with severe systemic illness. Large volumes of isotonic crystalloid fluids can be rapidly administered under pressure at 0.5 L/min through a 12-gauge catheter in the jugular vein, using a 7.5 L garden weed killer spray pump. The administration of hypertonic saline followed by immediate access to drinking water is a practical method of providing fluid therapy to cows with severe mastitis. Circulating blood volume is increased and there is mild strong ion acidosis, improved renal function and changes in calcium and phosphorus homeostasis when compared to cows given a similar volume of 0.9% NaCl. Fluid therapy is covered extensively in Chapter 2.

Adjunctive therapy

Cytokines may be useful as adjunctive therapy with existing antimicrobials to improve therapeutic efficacy, particularly in lactating cows. Cytokines are natural regulators of the host defense system in response to infectious diseases. The combination of a commercial formulation of cefalexin with recombinant interleukin-2 consistently improved the cure rate of treating *S. aureus* mastitis by 20–30% compared to use of the antimicrobial alone.

Magnitude of response to therapy

The treatment of some causes of mastitis can be highly effective in removing infection from the quarter and returning the milk to normal composition. However, the yield of milk, although it can be improved by the removal of congestion in the gland and inflammatory debris from the duct system, is unlikely to be returned to normal in severe clinical cases, at least until the next lactation. The degree of...
infusing an intramammary preparation and farmers are reluctant to break the teat canal seal, but it may be necessary to do so if summer mastitis is prevalent in the area.

Prepartum antimicrobial therapy in heifers

Intramammary infusion of a cefapirin dry cow therapy preparation into pregnant heifers 10–12 weeks prepartum eliminated over 90% of the intramammary infection due to *S. aureus*, *Streptococcus* spp., coagulase-negative *Staphylococcus* spp. and coliforms. The SCCs of cured quarters were comparable to uninfected control quarters after parturition. At parturition, 24% of treated quarters were positive for the antimicrobial; however, no quarters were positive at 5 days postpartum.

Antimicrobial residues in milk and withholding times

Label instructions must be followed to insure that drug residues do not occur, especially from cows with a shorter than normal dry period. Antibiotic residue testing of the milk of a recently calved cow can be done if there is a suspicion of residues, but this is a misuse of a test designed for bulk tank milk testing and therefore suffers from problems with sensitivity and specificity.

Treatment and control of mastitis accounts for the largest percentage of antimicrobial use on dairy farms. Following treatment by the intramammary or parenteral route, the concentration of antimicrobial agents in the milk declines over time to levels that are considered safe and tolerable for humans. The duration of time for the concentrations to decline to acceptable limits is known as the withholding time or the withdrawal period during which the milk cannot be added to the bulk tank supply but must be withheld and discarded. The presence of residues in milk is a major public health concern that adversely affects the dairy industry, the practicing veterinarian and the perception the public has of the safety of milk for human consumption. The public perception of the safety of milk is crucial and veterinarians have a responsibility to respond to these concerns through public education and quality control of milk production.

Other serious consequences of antimicrobial residues in milk are their effect on the manufacture of dairy products and the potential development of antimicrobial sensitivity syndromes in humans. In most countries the maximum intramammary dose of antimicrobial agents is limited by legislation and the presence of detectable quantities of antimicrobial agents in milk constitutes adulteration. Attention has also been directed to the excretion of antimicrobial agents in milk from untreated quarters, after treatment of infected quarters and after their administration by parenteral injection or by insertion into the uterus. The degree to which this excretion varies widely between animals and in the same animal at different points in the lactation period, and differs from one antibiotic to another. Milk from cows subjected to dry period treatment is usually required to be withheld for 4 days after calving. The use of any dry period treatments in lactating cows causes prolonged retention of the antimicrobial in milk and is a most serious violation of the legislation.

Veterinarians have the responsibility to warn farmers of the need to withhold milk, and both should be aware of the withholding times of each product, details of which are usually required to be included on its label. Marking the cow in some way to remind the farmer, by application of a leg band or placing dye on the udder, is advisable.

Antimicrobial residue tests

Several cowside tests are available to detect antimicrobial residues in the milk of cows that have been treated for mastitis. The goal of cowside testing is to assist in the production of high-quality, antimicrobial-residue-free milk from dairy herds. To be consistent with the intent of a quality assurance program, cowside testing would be used only on cows recently treated with antimicrobial agents and only after appropriate milk withholding times had been followed. The ideal test would have a high sensitivity and high specificity.

Most of the cowside screening tests for antimicrobial residues are imperfect because of a high rate of false-positive results when used on field samples. The direct costs to producers can be high because of the unnecessary disposal of milk and imposition of fines and penalties. False-positive results also cause the unnecessary culling of some cows, and concern about the interpretation of positive assay results, the appropriateness of withholding periods and the safety of milk creates mistrust among consumers, producers, veterinarians and regulatory personnel. The specificity of four commercially available tests ranged from 0.78–0.95. None of the test kits has been validated to meet performance standards for sensitivity and specificity. This applies to individual cow samples, bulk tank milk samples and tanker truck samples.

The presence of naturally occurring bactericidal products in the milk of cows with acute and convalescent mastitis is the most likely cause of the false-positive results of the tests (such as Delvo-test) that are based on bacterial growth inhibition of beta-lactam antimicrobial agents. Immunglobulins, complement, lysozyme, lactoferrin and phagocytic cells are products of inflammation in the milk of cows with mastitis that can inhibit bacterial growth. The milk from cows with experimental endotoxin-induced mastitis is at increased risk for false-positive assay results using commercial residue tests. The incidence of false-positive results is very low in milk from cows that have not had a history of mastitis or antimicrobial therapy. Naturally occurring bactericidal products in mastitic milk can be removed by heating at 82°C for 5 minutes; this temperature does not denature antimicrobial agents present in milk. Heat treatment therefore appears to provide a very practical way to reduce false-positive results on milk from individual cows.

A sample of milk can be submitted for antimicrobial residue testing up to three times. First, a producer may test a sample from a specific cow at the end of her withholding period. Second, milk is sampled at the tanker truck level. Third, should the tanker truck sample have positive results, bulk tank milk samples from each dairy herd that contributed to that tanker truck are tested.

There is a need for validation of the diagnostic assays used to detect antimicrobial residues in milk. Acceptance of assays for regulatory purposes must be based on protocols that include field estimates of assay performance before the assays are used by the public. Three strategies have been suggested to balance public health concerns with economic concerns of dairy producers caused by false-positive results:

- Retest samples that yield positive results with a confirmatory assay of specificity close to 100%. Only those samples that also yield positive results on the second assay are considered to be positive for violative residues
- Recalibrate the assay to increase specificity. This will usually result in loss of sensitivity
- Use an alternative assay of higher specificity

It is suggested that regulatory monitoring of residues at a national level will be best served by use of a combination of at least two assays: initial screening with a highly sensitive and inexpensive assay followed by confirmation testing with an assay of high specificity (> 99%) that can quantify the concentration of the antimicrobial residue. All tanker samples that yield positive results with a screening assay should be rechecked with a quantitative assay. If the quantitative assay detects a concentration
greater than the safe level, safe concentration or tolerance level, only then would the milk be deemed to have a residue and fines and penalties be imposed. The complex dynamics of current milk residue tests discourage practitioners from recommending testing procedures to dairy producers.

As an approximate guide, the recommended periods for which milk should be withheld from sale after different methods of antimicrobial administration are (in times after last treatment):
- Udder infusion in a lactating cow – 72 hours
- Parenteral injection, one only – 36 hours
- Parenteral injections, series of – 72 hours
- Antimicrobial agents parenterally in long-acting bases – 10 days
- Intraterine tablet – 72 hours
- Dry cow intramammary infusion – to be administered at least 4 weeks before calving and the milk withheld for at least 96 hours afterwards.

**Permanently drying off chronically affected quarters**

If a quarter does not respond to treatment and is classified as incurable, the affected animal should be isolated from the milking herd or the affected quarter may be permanently dried off by inducing a chemical mastitis. Historically used methods, arranged in decreasing order of severity, are infusions of:
- 30–60 mL of 3% silver nitrate solution
- 20 mL of 5% copper sulfate solution
- 100–300 mL of 1:500, or 300–500 mL of a 1:2000 acriflavine solution.

If a severe local reaction occurs, the quarter should be milked out and stripped frequently until the reaction subsides. If no reaction occurs, the quarter is stripped out 10–14 days later. Two infusions of these solutions may be necessary.

The best method for permanently drying off a quarter is infusion of 120 mL of 5% povidone–iodine solution (0.5% iodine) after complete milk-out and administration of flunixin meglumine (1 mg/kg BW, intravenously). This can cause permanent cessation of lactation in the quarter but does not alter total milk production by the cow. If the goal is chemical sterilization, then three daily infusions of 60 mL of chlorhexidine suspension should be administered after complete milk-out. The majority of treated cows (5/7) returned to milk production in the quarter in the subsequent lactation.

The infusion of 60 mL of chlorhexidine, followed by milking out at the next subsequent milking and repeat of the infusion 24 hours after the initial treatment is also effective in making infused quarters nonfunctional within 14–63 days. Histological evaluation of the infused quarters revealed that secretory tissie had involuted to a nonsecretory state and appeared similar to blind or nonfunctional quarters. However, as noted above, milk production may return in the gland in the subsequent lactation.

**Review Literature**

Mastitis pathogens of cattle

In the sections which follow, the special features of each mastitis associated with one or a group of pathogens will be described using the usual format of the book. Mastitis in cattle is categorized as being associated with contagious, teat skin opportunistic or environmental pathogens, and as being common or less common. The features that are unique to the diagnosis, treatment and control of each mastitis pathogen will be outlined but details applicable to all causes of mastitis have been presented above.

Mastitis of cattle associated with common contagious pathogens

**STAPHYLOCOCCUS AUREUS**

**Etiology** Staphylococcus aureus is a major pathogen of the mammary gland and a common cause of contagious bovine mastitis. *S. aureus* also causes mastitis in sheep and goats.

**Epidemiology** Major cause of mastitis in dairy herds without an effective mastitis control program. Prevalence of infection 50-100%, prevalence of 1-10% in herds with low bulk tank milk SCCs. 50% in high-SCC herds, quarter infection rate 10-25% in high-SCC herds. Source of infection is infected udder, infection transmitted at milking. Chronic or subclinical *S. aureus* mastitis is of major economic importance.

**Clinical findings**
- Chronic *S. aureus* mastitis is most common and is characterized by high SCC and gradual induction of udder, drop in milk yield and atrophy with occasional appearance of clots in milk or wateriness.
- Acute and peracute *S. aureus* mastitis most common in early lactation. Acute swelling of gland with fever, milk is abnormal with thick clots and pus; gangrene of gland and teat in peracute form. Systemic reaction with anorexia, toxemia, fever, ruminal stasis.

**Clinical pathology** Culture individual cow milk sample; indirect tests are high SCC and California Mastitis Test results.

**Diagnosis verification** Culture milk for pathogen.

**Differentiation diagnostic**
- Peracute mastitis
- Peracute coliform mastitis
- Aracobacterium (formerly Actinomyces or Corynebacterium) pyogenes mastitis
- Parturient parotis
- Acute and chronic mastitis. Not clinically distinguishable from other causes of mastitis. Must culture milk.

**Treatment**
- Lactating cows - cure rates for lactating cows with subacute staphylococcal mastitis less than 50%. Intramammary infusions daily for at least 3 days, preferably 5-8 days.
- Peracute mastitis - antimicrobial agents parenteral and intramammary that are beta-lactamase-resistant, fluid and electrolyte therapy.
- Dry cow therapy - chronic or subclinical mastitis best treated at drying off with long-acting intramammary antimicrobial infusions that are beta-lactamase-resistant.

**Control**
- Prevent new infections by early identification, culling infected cows and good milking procedures, including hygienic washing and drying of udders and teats before milking and postmilking girmedial teat dips. Regular milking machine maintenance. Consider segregation of infected cows.
- Eliminate existing infections by dry cow therapy.
- Immunization with vaccines may be possible in future.

**EPIDEMIOLOGY**

**Occurrence and prevalence of infection**

Coagulase-positive staphylococci. Historically, *S. aureus* was one of the most common causes of bovine mastitis in dairy cattle worldwide. In the last 25 years, the prevalence of infection and the occurrence of clinical mastitis due to *S. aureus* has decreased in herds using effective mastitis control measures. However, surveys indicate that 50-100% of herds may be infected. In low-SCC herds, the prevalence of infection in cows ranges from 1-10%. In other herds, especially those with high SCCs, up to 50% of cows may be infected with *S. aureus*, with quarter infection rates ranging from 10-25%. The prevalence of infection of *S. aureus* in heifers at parturition can range from 5-15%. The majority of intramammary infections due to *S. aureus* are subclinical. The incidence of clinical mastitis due to *S. aureus* is dependent on its prevalence of infection in the herd. With an effective mastitis control program, the most common causes of clinical mastitis are the environmental pathogens. However, in some herds with a low rolling SCC, incidence of clinical mastitis due to *S. aureus* ranges from 190-240 cases/100 cows/year, with about 47% of the clinical cases being *S. aureus*.

**Source of infection and method of transmission**

*S. aureus* is ubiquitous in the environment of dairy cattle. The infected mammary gland of lactating cows is the major reservoir and source of the organism. The prevalence of intramammary infection in primiparous heifers at parturition ranges from 2-50% and may represent an important reservoir of infection in herds with a low prevalence of infection. The organism may be present on the skin of the teats and external orifices of heifers, bedding materials, feedstuffs, housing materials, nonbovine animals on the farm, and equipment. In herds with a high prevalence of infection (> 10% of cows), the organism was present in bedding, the hands and noses of dairy herd workers, insects and water supplies. Transmission between cows occurs at the time of milking by contaminated milkers’ hands and teat cup liners. Although *S. aureus* can multiply on the surface of the skin and provide a source of infection for the udder, the teat skin lesions are usually infected originally from the udder,
and teat skin is a minor source of infection.

The hornfly (Hameotobia irritans) is an important vector for transmitting S. aureus mastitis in heifers, particularly in herds with scabs on the teat ends of heifers. Prevention of high populations of flies in heifers is therefore needed to decrease new infections in this group.

**Risk factors**

**Animal risk factors**
Several animal risk factors influence the prevalence of infection and the occurrence of clinical mastitis due to S. aureus.

**Local defense mechanisms**
Abrasions of the teat orifice epithelium are an important risk factor for S. aureus mastitis. In experiments, teat canal infection or colonization may develop in 95% of experimentally abraded teat canal orifices compared to 53% in control quarters. Chapping of the teats and thickness of the teat barrel are correlated and significantly influence recovery of S. aureus from the skin.

**Colonization with minor pathogens**
The presence of minor pathogens such as coagulase-negative staphylococci protects against new intramammary infections associated with the major pathogen S. aureus. This may be the result of an elevated SCC or an antimicrobial-like substance provided by the coagulase-negative staphylococci that inhibits the growth of S. aureus. Conversely, quarters infected with coagulase-negative staphylococci may be more susceptible to new infections with S. agalactiae. Quarters that are infected with C. bovis are protected against S. aureus infection but not protected against most streptococcal species.

**Parity of cow**
The prevalence of intramammary infection and subclinical infection due to S. aureus increases with parity of the cow. This is probably due to the increased opportunity of infection with time and the prolonged duration of infection, especially in a herd without a mastitis control program.

**Presence of other diseases**
The presence of periparturient diseases such as dystocia, parturient paresis, retained placenta and ketosis has been identified as a risk factor for mastitis. The occurrence of sole ulcers in multiple digits may be associated with S. aureus in the first lactation.

**Heredity**
Experimentally, the presence of certain bovine lymphocyte antibodies increased the susceptibility to S. aureus infection but heritability estimates of susceptibility after experimental challenge were low and unstable.

**Immune system**
The infection rate of S. aureus is dependent on the ability of the immune system to recognize and to eliminate the bacteria. Staphylococcal antibodies are present in the blood of infected cows but they appear to afford little protection against mastitis associated with S. aureus. This may be due to the low titer of the antibodies in the milk. Antibody titers in the serum rise with age and after an attack of mastitis.

The development or persistence of S. aureus mastitis depends on the interaction between invading bacteria and the host’s defense system, principally the somatic cells in an infected gland, which are more than 95% polymorphonuclear cells. The number of bacteria isolated from milk samples of S. aureus-infected mammary glands is characterized by a cyclic increase and decrease concomitant with an inverse cycling of the SCC. This relationship between SCC and numbers of bacteria indicates that the cells within the mammary gland have a central role in the pathogenesis of S. aureus infection. There appear to be qualitative changes in the ability of the animal’s somatic cells to phagocytose the bacteria. During the period of high SCC, the cells are able to kill bacteria 9000 times more efficiently than during the low-SCC period. The relative inability of the polymorphonuclear cells to kill bacteria during the low-SCC period may explain the source of reinfection. Phagocytosis and killing of the bacteria may also be inefficient because of low concentrations of opsonins, a lack of energy source, and the presence of casein and fat globules in the milk. The function of the intramammary polymorphonuclear cell (somatic cells) may also be affected by immunosuppression induced by cortisol and dexamethasone in treated cows.

**Environmental and management risk factors**
Several herd-level management risk factors are important for the spread of S. aureus. Poor teat and udder cleaning can allow spread of the organism among quarters of the same cow, and can allow contamination of milking units, which are commonly transferred among cows without washing or rinsing. The use of high-line parlors is a risk; this may be due to the greater fluctuation in vacuum, especially when units are removed, leading to a greater occurrence of teat end impacts in which bacteria in the milking unit may enter the teat canal to establish a new udder infection.

Extensive surveys reveal that management procedures that are most effective in reducing infection rates and cell counts associated with infections with S. aureus are:
- Postmilking teat dipping
- Maintaining a good supply of dry bedding for housed cows
- Thorough disinfection of the teat orifice before infusing intramammary preparations
- Milking clinical cases last.

Failure to use these management techniques will increase the risk of intramammary infection with S. aureus.

**Pathogen risk factors**

**Virulence factors**
S. aureus has several virulence factors that account for its pathogenicity and persistence in mammary tissue in spite of adequate defense mechanisms and antimicrobial therapy. Most isolates from cattle appear to be host-adapted and different from human S. aureus isolates. S. aureus has the ability to colonize the epithelium of the teat and the streak canal, and can adhere and bind to epithelial cells of the mammary gland. The specific binding is to the extracellular matrix proteins fibronectin and collagen, which can induce the epithelial cell to internalize the organism, protecting it from both exogenous and endogenous bactericidal factors. Some strains of S. aureus are capable of invading bovine mammary epithelial cells in culture, and the invasion process requires eukaryotic nucleic acid and protein synthesis as well as bacterial synthesis.

Some strains of S. aureus produce toxins, some of which may cause phagecytic dysfunction. The beta toxin, or a combination of alpha toxins and beta toxins, is produced by most pathogenic strains isolated from cattle but its pathogenic significance is uncertain. The beta toxin damages bovine mammary secretory epithelial cells, increases the damaging effects of alpha toxin, increases the adherence of S. aureus to mammary epithelial cells and increases the proliferation of the organism.

**Eco**
The effect of S. aureus on bovine mammary gland health depends on the interaction of the bacterium with its environment, which can vary significantly from herd to herd. The bovine mammary gland environment is complex and dynamic, and the interactions between the bacterium and the host environment play a critical role in the development of bovine mastitis.

**Ze**
The bacterium S. aureus is a common pathogen in bovine mastitis, and its presence can have significant impacts on milk quality and production.

**L-form**
L-forms of S. aureus are thought to be associated with certain types of infections, such as chronic or persistent infections, but their role in bovine mastitis is not well understood.

Mastitis of cattle associated with common contagious pathogens

STAPHYLOCOCCUS AUREUS

Microabscesses in the mammary gland so that it is protected from normal defense mechanisms, including phagocytic activity from neutrophils. The difficulty in removing staphylococci from an infected quarter is due largely to the bacterium’s ability to survive in intracellular sites. There is also an ability to convert to a nonsusceptible L-form when exposed to antimicrobial agents, and to return to standard forms when the antimicrobial is withdrawn.

Genotype of strains

Phage typing and ribotyping can be used to classify strains from clinical and subclinical *S. aureus* mastitis. DNA fingerprinting techniques, using polymerase chain reaction, are also being used to differentiate various strains of the organism. A large number of different types of *S. aureus* can be isolated from cases of bovine mastitis but a few types predominate within different countries. Surveys have found that only a small number of genotypes cause most cases of *S. aureus* mastitis, which may be useful information in determining the dynamics of infection in a herd and how infection spreads from cow to cow. Fine-structure molecular epidemiological analysis of *S. aureus* recovered from cows in the USA and Ireland indicates that only a few specialized clones of *S. aureus* are responsible for the majority of cases of bovine mastitis, and that these clones have a broad geographical distribution. A predominant strain is usually responsible for most clinical and subclinical *S. aureus* infections in a herd, and it is currently believed that *S. aureus* is a clonal organism that spreads from cow to cow. Moreover, most strains isolated from milk are different from strains isolated from the teat skin. In other words, most *S. aureus* strains isolated from mastitis demonstrate both host and site specificity. This has important implications in the control of mastitis associated with *S. aureus*, as a rational and effective strategy for control of intramammary infections should be directed against clones that commonly cause disease.

Economic importance

The overall prevalence of mastitis due to *S. aureus* is much higher than for *S. agalactiae*, and the need for culling causes much greater economic consequences. The risk of new infections is of continuing concern. Response to treatment is comparatively poor, and satisfactory methods for the eradication of staphylococcal mastitis from infected herds have yet to be devised.

Zoonotic implications

The presence of *S. aureus* in market milk may present a degree of risk to the consumer because of the organism’s capacity to produce enterotoxins and a toxic shock syndrome toxin, which cause serious food poisoning. Mastitic milk does not constitute any large risk for *S. aureus* enterotoxin food poisoning.

PATHOGENESIS

The disease can be reproduced experimentally by the injection of *S. aureus* organisms into the udder of cattle and sheep but there is considerable variation in the type of mastitis produced. This does not seem to be due to differences in virulence of the strains used, although strain variations do occur, but may be related to the size of the inoculum used or, more probably, to the lactational status of the udder at the time of infection. It is possible to induce *S. aureus* infection in the bovine teat cistern; the teat tissues are able to mount a marked local inflammatory response but in spite of large numbers of neutrophils that invade the teat, they are unable to control the infection, except when the numbers of bacteria are low.

Infection during early lactation may result in the peracute form of mastitis, with gangrene of the udder. During the later stages of lactation or during the dry period, new infections are not usually accompanied by a systemic reaction but result in the chronic or acute forms. Chronic *S. aureus* mastitis in cows has been converted to the peracute, gangrenous form by the experimental production of systemic septicemia. In the gangrenous form, the death of tissue is precipitated by thrombosis of veins causing local edema and congestion of the udder. *S. aureus* are the only bacteria that commonly cause this reaction in the udder of the cow, and the resulting toxemia is due to bacterial toxins and tissue destruction. Secondary invasion by *E. coli* and *Clostridium* spp. contributes to the severity of the lesion and production of gas.

The pathogenesis of acute and chronic *S. aureus* mastitis in the cow is the same, the variation occurring only in degree of involvement of mammary tissue. In both forms each focus commences with an acute stage characterized by proliferation of the bacteria in the collecting ducts and, to a lesser extent, in the alveoli. In acute mastitis the small ducts are quickly blocked by fibrin clots, leading to more severe involvement of the obstructed area.

In the chronic form there are fewer foci of inflammation and the reaction is milder; the inflammation is restricted to the epithelium of the ducts. This subsides within a few days and is replaced by connective tissue proliferations around the ducts, leading to their blockage and atrophy of the drained area. The leukocyte infiltration into the stroma, the epithelial lining and the lumina indicate an obvious deficiency of secretory and synthesizing capacity due to limitation of the alveolar lumina and the distension of the stroma area.

A characteristic of chronic *S. aureus* mastitis that is important in its diagnosis is the cyclical shedding of the bacteria from the affected quarter. Parallelizing this variation is a cyclical rise and fall in the number of polymorphonuclear cells in the milk, and their capacity to phagocytose bacteria. In some cases abscesses develop and botryomycosis of the udder, in which granulomata develop containing Gram-positive cocci in an amorphous eosinophilic mass, is also seen.

CLINICAL FINDINGS

**Chronic Staphylococcus aureus mastitis**

The most important losses are caused by the chronic form or subclinical form of mastitis. Although up to 50% of cattle in a herd may be affected, only a few animals will have abnormalities recognizable by the milker. Many cases are characterized by a slowly developing induration and atrophy with the occasional appearance of clots in the milk or watteryness of the first streams. The SCC of the milk is increased, as well as the CMT results of infected quarters, but the disease may go unnoticed until much of the functional capacity of the gland is lost. The infection can persist and the disease may progress slowly over a period of many months.

**Acute and peracute Staphylococcus aureus mastitis**

Acute and peracute staphylococcal mastitis are rare but do occur and can be fatal, even if aggressively treated.

**Acute *S. aureus* mastitis** occurs most commonly in early lactation. There is severe swelling of the gland and the milk is purulent or contains many thick clots. Extensive fibrosis and severe loss of function always result.

**Peracute *S. aureus* mastitis** occurs usually in the first few days after calving and is highly fatal. There is a severe systemic reaction with elevation of the temperature to 41–42°C (106–107°F), rapid heart rate (100–120 beats/min), complete anorexia, profound depression, absence of ruminal movements and muscular weakness, often to the point of recumbency. The onset of the systemic and local reactions is sudden. The cow may be normal at one milking and recumbent and comatose at the next. The affected quarter is grossly swollen, hard and sore to touch, and causes severe lameness on the affected side.
Gangrene is a constant development and may be evident very early. A bluish discoloration develops that may eventually spread to involve the floor of the udder and the whole or part of the teat, or may be restricted to patches on the sides and floor of the udder. Within 24 hours the gangrenous areas become black and oozing serum and may be accompanied by subcutaneous emphysema and the formation of blisters. The secretion is reduced to a small amount of bloodstained serous fluid without odor, dots or flakes. Unaffected quarters in the same cow are often swollen, and there may be extensive subcutaneous edema in front of the udder caused by thrombosis of the mammary veins. Toxemia is profound and death usually occurs unless early, appropriate treatment is provided. Even with early treatment the quarter is invariably lost and the gangrenous part may remain attached for weeks. After separation, pus drains from the site for many more weeks before healing finally occurs.

CLINICAL PATHOLOGY
Culture of individual cow milk
Bacteriological culture of milk is the best method for identifying cows with S. aureus intramammary infection.25 A problem in the laboratory identification of S. aureus is that bacteria are shed cyclically from infected quarters, so that a series of samples are necessary to increase overall test sensitivity. The sensitivity of a single sample may be as low as 75%. Factors that have the greatest impact on the sensitivity of culture, in order of importance, are:

- The type of milk sample
- The volume of milk cultured
- The time interval between repeated milk sample collection strategies.26

Quarter samples taken on day 1 and repeated either on day 3 or 4, and cultured separately using 0.1 mL of milk for culture inoculum, were predicted to have sensitivities of 90–95% and 94–99%, respectively.26 Repeated quarter samples collected daily and cultured separately gave a sensitivity of 97% and a specificity from 97–100%.27 Culturing of composite milk samples instead of individual quarter samples increases the number of false-negative results in diagnosing S. aureus mastitis,28 but the sensitivity of composite samples can be increased by using 0.05 mL of milk for inoculation. Freezing of milk samples before processing either does not affect the bacterial count or enhances it by about 200%; the latter response is attributed to fracturing of cells containing viable S. aureus bacteria. Bacterial counts of more than 200 cfu/mL are commonly used as a criterion for a positive diagnosis of infection.

Culture of bulk tank milk
The culture of 0.3 mL of bulk tank milk for S. aureus using special Baird–Parker culture media is a practical method for detecting the organism in bulk tank milk and monitoring its spread in dairy herds,29 the sensitivity and specificity for detection of the bacteria ranged from 90–100%.

Somatic cell counts and California Mastitis Test
In an attempt to decrease the cost of sampling all quarters for culture, an alternative strategy is to use the SCC as a screening test in order to identify which cows to culture for S. aureus. For all intramammary infections, the sensitivity and specificity of SCC range from 15–40% and 92–99%, respectively. Composite milk sample SCCs have a low sensitivity, ranging from 31–54% for detecting cows with S. aureus.30 Individual quarter SCCs have a higher sensitivity, ranging from 71–95% depending on the study and cutpoint chosen, but quarter sampling is impractical as SCC is usually performed on a composite sample.30 Both composite and quarter milk SCC testing result in an unacceptably high proportion of infected cows being missed30,31 and are therefore not currently recommended as a screening test if the goal is to identify all cows with a S. aureus intramammary infection in the herd.

The CMT has also been used as a screening test to identify quarters or cows to culture. Using a CMT trace, 1, 2, or 3 to indicate the presence of an intramammary infection produced a range of sensitivities from 0.47–0.96 and specificities of 0.41–0.80.30

In summary, culture of quarter milk samples (preferably) or a composite milk sample is superior to a quarter SCC or CMT for the diagnosis of S. aureus intramammary infection.30 Culture is strongly preferred if it is important to identify all positive cows in a herd because the sensitivity of indirect tests (such as SCC, CMT) is inadequate.

Enzyme-linked immunosorbent assays for antibody in milk
ELISA tests for detecting S. aureus antibody in milk have been developed32,33 but are not widely used. Rapid laboratory tests incorporating these ELISAs, including a Staph-zym test, have demonstrated 84–90% accuracy in identifying staphylococci.32

Acriflavine disk assay
The acriflavine disk assay is a practical, accurate method for differentiating S. aureus isolates from non-S. aureus staphylococci.33

NECROPSY FINDINGS
In peracute staphylococcal mastitis, the affected quarter is grossly swollen and may contain bloodstained milk dorsally but only serosanguineous fluid ventrally. There is extreme vascular engorgement and swelling, often progressing to moist gangrene of the overlying skin. Bacteria are not isolated from the bloodstream or tissues other than the mammary tissue and regional lymph nodes. Histologically there is coagulation necrosis of glandular tissue and thrombosis of veins.

In milder forms of staphylococcal mastitis the invading organisms often elicit a granulomatous response. Microscopically, such 'botryomycotic' cases are characterized by granulomas with a central bacterial colony and by progressive fibrosis of the quarter.

Samples for confirmation of diagnosis
- Bacteriology – chilled mammary tissue, regional lymph node
- Histology – fixed mammary tissue

DIFFERENTIAL DIAGNOSIS
Because of the occurrence of the peracute form in the first few days after parturition, the intense depression and inability to rise, the dairy producer may conclude that the cow has parturient paresis, which is characterized by weakness, recumbency, hypothermia, rumen stasis, dilated pupils, tachycardia with weak heart sounds and a rapid response to intravenous calcium gluconate. The mammary gland is usually normal in parturient paresis.

Peracute S. aureus mastitis is characterized by marked tachycardia, fever, weakness and evidence of severe clinical mastitis with swelling, heat, abnormal milk with serum and blood, and sometimes gas in the teat and often with gangrene of the teat up to the base of the udder. Other bacterial types of mastitis, particularly E. coli and P. pyogenes, may cause severe systemic reactions but gangrene of the quarter is less common.

Peracute coliform mastitis is a much more common cause of severe mastitis than S. aureus mastitis. The chronic and acute forms of staphylococcal mastitis are indistinguishable clinically from many other bacterial types of mastitis and bacteriological examination is necessary for identification.

TREATMENT
The bacteriological cure rates for the treatment of S. aureus mastitis with either intramammary infusion or parenteral antimicrobial administration are notoriously less than satisfactory, particularly in the lactating cow. Bacteriological cure rates after antimicrobial treatment seldom
exceed 50% and infections commonly persist throughout the lifetime of the cow. There are three likely reasons inadequate penetration of the antimicrobial agent to the site of infection, formation of L-forms of S. aureus, and beta-lactamase production.

Inadequate penetration of antimicrobial agent

There is inadequate penetration of the antimicrobial agent into the site of intramammary infection in the lactating cow and the organism survives in phagocytes that are inaccessible. There may also be inactivation of the antimicrobial by milk and serum constituents, and the formation of L-forms of the organism during treatment, varying between 0% and 80% of bacteria.

Antimicrobial resistance

Antimicrobial resistant strains of S. aureus occur and are often beta-lactamase producers, the enzyme conferring resistance to beta-lactam antimicrobial agents such as penicillin G, penethamate, ampicillin and amoxicillin. Cloxacillin and nafcillin are effective, but only against Gram-positive bacteria; they are less effective against nonlactamase staphylococci. Clavulanic acid added to amoxicillin overcomes this beta-lactamase resistance. So does cloxacillin added to ampicillin, and this is made use of in a popular intramammary formulation. First- and third-generation cephalosporins and erythromycin are effective against beta-lactamase-producing staphylococci, and first- and third-generation cephalosporins are also effective against Gram-negative bacteria. A cephalin dry cow product administered to heifers with S. aureus infections resulted in bacteriological cure and left the quarters clear well into their first lactation. Intramammary clotrimazol and ampicillin is generally considered to be the preferred initial treatment for S. aureus mastitis because beta-lactamase production by S. aureus is sufficiently common.

Antimicrobial therapy for S. aureus subclinical mastitis during the lactating period is not economically attractive because of low bacteriological cure rates, discarding of milk during the withholding period and the lack of an economically beneficial increase in production following treatment. Dry cow treatment at the end of lactation is much more effective, being successful in 40–70% of cases, although treatment should be attempted in heifers infected early in lactation. Cows that are infected with S. aureus should be appropriately identified, segregated if possible and milked last or with separate milking units. Culling of infected cows is also an option for consideration, but a detailed economic analysis of this popular recommendation is lacking.

Lactating cow therapy

The treatment of clinical cases of S. aureus mastitis using intramammary antimicrobial infusions is less than satisfactory but is often done. However, clinical recovery following therapy does not necessarily eliminate the infection and some of the published literature on cure rates has not made the distinction between clinical and bacteriological cure rates. In general, the cure rate depends on the duration of infection, the number of quarters infected, whether the strain of S. aureus is a beta-lactamase producer, the immune status of the cow, the antimicrobial agent administered and the duration of treatment. Current recommendations to ensure the best treatment success rate are to combine intramammary and parenteral antimicrobial treatment or use extended intramammary treatment for 4–8 days. Penicillin G is regarded as the antimicrobial agent of choice for S. aureus strains that are penicillin-sensitive.

The following intramammary infusions, given daily at 24-hour intervals for three treatments (unless stated otherwise) have been used for the treatment of clinical cases of S. aureus mastitis, with expected clinical cure rates of about 50–60% in lactating cows. Subclinical cases are left until the cow is dried off:

- Sodium cloxacillin (200–600 mg for three infusions)
- Tetracyclines (400 mg)
- Penicillin–streptomycin combination (100 000 units – 250 mg)
- Penicillin–tlyosin combination (100 000 units – 240 mg)
- Novebacin (250 mg per infusion for three infusions)
- Cephalosporins – most strains of S. aureus are sensitive to cephalixin
- Pirlimycin–extended therapy (two 50 mg doses, 24 hours apart, then 36-hour withhold, then cycle repeated twice, equivalent to infusing at 0, 24, 60, 84, 120, and 144 hours).

In a study of 184 cases of subclinical S. aureus mastitis in New York, commercially available intramammary infusions were not significantly more effective than untreated controls (43% bacteriological cure), with the following bacteriological cure rates: erythromycin (65%), penicillin (65%), cloxacillin (47%), amoxicillin (43%), and cephalin (43%).

A slightly more effective treatment for subclinical S. aureus intramammary infection, with a cure rate of 50%, is simultaneous intramammary infusion of amoxicillin (62.5 mg) and intramuscular injection of procaine penicillin G (9 000 000 units). This study was the first to demonstrate that combined parenteral and intramammary therapy was more effective than intramammary infusion alone.

Because of the persistence of the infection in each herd the final choice of the antimicrobial to be used should be based on the culture and susceptibility test; the latter is to determine whether the predominant S. aureus strain in the herd is a beta-lactamase producer; this is because beta-lactamase-producing strains are harder to cure and require a specific antibiotic protocol. The bacteriological cure rate for penicillin-sensitive infections treated with parenteral and intramammary penicillin G was 76%, compared to beta-lactamase–producing strains treated with parenteral and intramammary amoxicillin–clavulanic acid (29%).

The application of cytokines as an adjunct to antimicrobial therapy may help to increase the number of phagocytes in the mammary gland and enhance cell function. The experimental intramammary infusion of recombinant interleukin into infected or uninfected mammary glands elicited an influx of polymorphonuclear leukocytes exhibiting subsequent enhanced activity and increased the cure rate 20–30% in quarters infected with S. aureus.

A novel method for decreasing the transmission of S. aureus within a herd is to selectively cease lactation in infected quarters of lactating cattle. The best method for permanently drying off a quarter is infusion of 120 mL of 5% povidone–iodine solution (0.5% iodine) after complete milk-out and administration of flunixin meglumine (1 mg/kg BW, intravenously). Therapeutic cessation of milk production in one quarter does not alter daily milk production but does decrease individual cow SCC and its contribution to the bulk tank milk SCC. The final outcome of selectively drying off infected quarters is a decrease in the rate of new intramammary infections in the herds and a lowering in the bulk tank milk SCC.

Peracute mastitis

Early parenteral treatment of peracute cases with adequate dosing of antimicrobials such as trimethoprim–sulfonamide or penicillin is deemed necessary to improve the survival rate. When penicillin is used the initial intramuscular injection should be supported by an intravenous dose of crystalline penicillin, with subsequent intramuscular doses to maintain the highest possible blood level of the antimicrobial over a 4–6-day period; tannecillin or penemethic acid is preferred to achieve this. Intramammary infusions are of little value in such cases because of failure of the drugs to diffuse into the gland. The intravenous administration of large quantities
of electrolyte solutions is also recommended. Hypertonic saline, as recommended for peracute coliform mastitis, has not yet been evaluated but may be indicated. Frequent massage of the udder with hot wet packs and milking out the affected gland is recommended. Oxytocin is used to promote milk-down but is relatively ineffective in severely inflamed glands. Surgical amputation of the teat may be indicated to promote drainage of the gland, but only in cows with necrotic teats.

Dry cow therapy
It has become a common practice to leave chronic S. aureus cases until they are dried off before attempting to eliminate the infection. The material is infused into each gland after the last milking of the lactation and left in situ. The major benefits of dry cow therapy are the elimination of existing intramammary infections and prevention of new intramammary infections during the dry period. In addition, milk is not discarded and bacteriological cure rates are superior to those obtained during lactation.

The factors associated with a bacteriological cure after dry cow therapy of subclinical S. aureus mastitis have been examined. The probability of cure of an infected quarter decreased when:

- SCC increased
- Age of cow increased
- Another quarter was infected in the same cow
- The infection was in a hind quarter
- The percentage of samples that were positive for S. aureus was higher before drying off.

Cows with more than one infected quarter were 0.6 times less likely to be cured than cows with one infected quarter. The cure rate of cows with one infected quarter of 700 000, the probability of cure is 92%. In a 3-year-old cow with one quarter infected and a SCC of 2300 000 is 36%. In a 3-year-old cow with one quarter infected and a SCC of 2300 000, the probability of cure is 92%. In a 3-year-old cow with one quarter infected and a SCC of 2300 000, the probability of cure is 92%. When all else has failed is to permanently remove from the herd by designating them as 'do not breed' and culling when it is economically opportune.

Most intramammary antimicrobial infusions are satisfactory for dry cow therapy provided they are combined with slow-release bases. Bacteriological cure rates vary between herds from 25-75% and average about 50%. The use of parenteral antimicrobials such as oxytetracycline along with an intramammary infusion of cephalirin did not improve the cure rate for S. aureus.12

CONTROL
Because of the relatively poor results obtained in the treatment of staphylococcal mastitis, any attempt at control must depend heavily on effective methods of preventing the transmission of infection from cow to cow. S. aureus is a contagious pathogen, the udder is the primary site of infection, and hygiene in the milking parlor is of major importance. To reduce the source of the organism, a program of early identification, culling, and segregation is important to control S. aureus mastitis in a dairy herd, although successful implementation of all three aspects is challenging. Satisfactory control of S. aureus mastitis has historically been difficult and unreliable; however, at the present time the quarter infection rate can be rapidly and profitably reduced from the average level of 30% to 10% or less.

The strategies and practices described under the control of bovine mastitis later in this chapter are highly successful for the control of S. aureus mastitis when applied and maintained rigorously. The control program includes:

- Sanitary washing and cleaning of the udder before milking
- Regular milking-machine cleaning
- Teat dipping after milking. Teat dip containing 1% iodine or 0.5% chlorhexidine, either in 5-10% glycerine, is completely effective against S. aureus mastitis.13 The program helps to eliminate infected quarters and reduces the new infection rate by 50-65% compared to controls. The disinfection of hands or use of rubber gloves provides additional advantages.
- Dry cow treatment on all cows
- Culling cows with chronic mastitis
- Milking infected cows last (very difficult to implement in free stall housing or pasture feeding).

An alternative but radical control strategy when all else has failed is to permanently dry off the infected quarter using iodine infusion.

Immunization against S. aureus mastitis has been widely researched for 100 years. Different vaccines based on cellular or soluble antigens with and without adjuvants have been given to dairy cows but protection against infection and clinical disease has been unsatisfactory when used in the field. Currently available vaccines are autogenous bacterins (made to order using isolates from clinical cases on the farm) or contain one or more S. aureus strains that are believed to provide good cross-protection. The goals of such vaccines are to decrease the severity of clinical signs and increase the cure rate, particularly when administered to heifers before they calve. Vaccination has also been used simultaneously with antimicrobial therapy during lactation or at dry-off in an attempt to augment the cows immune response, with mixed success. Development of an effective S. aureus vaccine remains one of the most important issues confronting control of infectious diseases in cattle.

REVIEW LITERATURE

REFERENCES
STREPTOCOCCUS AGALACTIAE

Etiology Streptococcus agalactiae is a major pathogen of the mammary gland and a common cause of contagious bovine mastitis.

Epidemiology Major cause of mastitis in dairy herds without an effective mastitis control program. Prevalence of infection 10–50% of cows and 25% of quarters. In herds with effective control program prevalence less than 10% of cows. Can be eliminated from herd with treatment and control. Highly contagious obligate pathogen. Infection is transmitted at milking.

Clinical findings Individual repeated episodes of subacute to acute mastitis are most common. Gland is swollen, warm, and milk is watery and contains clots. Gradual induction of udder if not treated.

Clinical pathology Culture of individual cow milk samples or bulk tank milk samples. Latex agglutination test

Necropsy findings Not important

Diagnostic confirmation Latex agglutination test for specific identification of organism

Differential diagnosis Cannot differentiate clinically from other causes of acute and chronic mastitis. Must culture milk.

Treatment Mastitis associated with S. agalactiae in lactating cows is sensitive to intramammary therapy with wide variety of antimicrobial agents resulting in high rate of clinical and bacteriological cures. Blist therapy (simultaneous treatment of all positive cows in a herd) commonly used to reduce prevalence of infection in herd.

Control Eradication is possible. Identify and treat infected quarters, culled infections cows, Premilking teat and udder sanitation, postmilking teat dipping, and dry cow therapy.

ETIOLOGY Streptococcus agalactiae. Infections with environmental streptococci are described in the next section.

EPIDEMIOLOGY Occurrence and prevalence of infection

S. agalactiae was the major cause of mastitis before the antimicrobial era and is still a significant cause of chronic mastitis where control procedures for contagious mastitis are not used. Herd prevalence rates of infection range from 11–47%. Typically, in a herd infected with the pathogen, prevalence of infection could be as high as 50% of cows, but more recent surveys indicate much lower within-herd prevalences, ranging from 8–10%. Where good hygienic measures and the efficient treatment of clinical cases are in general use, the prevalence of infection within a herd will be less than 10% of cows. Following the use of antimicrobial agents, S. agalactiae was superseded by Staphylococcus aureus as the major cause of bovine mastitis. In herds with a high bulk tank milk SCC, the probability is high that S. agalactiae infection is the most prevalent pathogen.

Source of infection S. agalactiae is a highly contagious obligate parasite of the bovine mammary gland.

The main source of infection is the udder of infected cows although, when hygiene is poor, contamination of the environment may provide an additional source. The teats and skin of cattle, milkers’ hands, floors, utensils and clothes are often heavily contaminated. Sores on teats are the commonest sites outside the udder for persistence of the organism. The infection may persist for up to 3 weeks on hair and skin and on manure and bricks. The importance of environmental contamination as a source of infection is given due recognition in the general disinfection technique of eradication.

Transmission of infection Transmission from animal to animal occurs most commonly by the medium of milking machines liners, hands, udder cloths and possibly bedding.

The streak canal is the portal of entry, although there is doubt as to how invasion into the teat canal and then gland occurs. Suction into the teat during milking or immediately afterwards does occur, but growth of the bacteria into the canal between milkings also appears to be an important method of entry. It is difficult to explain why heifers that have never been milked may be found to be infected with S. agalactiae, although sucking between calves after ingestion of infected milk or contact with infected inanimate materials may be sources of infection.

Risk factors There is no particular breed susceptibility but infection does become established more readily in older cows and in the early part of each lactation. Poor hygiene, incompetent milking personnel and machinery that is faulty or maladjusted are important risk factors. The most important risk factors are the failure to use postmilking teat dip and the selective or non-use of dry cow therapy. The use of a common wash rag or sponge is also a risk factor. Inadequate treatment of clinical cases of mastitis is also a frequent risk factor in infected herds.

S. agalactiae has the ability to adhere to the mammary gland tissue, and the specific microenvironment of the udder is necessary for growth of the organism. The virulence of various strains of the organism is related to differences in their ability to adhere to the mammary epithelium. Bacterial ribotyping has been used to characterize strains of the organism to determine their geographical distribution. The physical characteristics of the teat canal may influence the susceptibility to streptococcal infection. The mechanisms used by S. agalactiae to penetrate the teat canal are influenced more by the diameter of the teat canal lumen, as reflected by the peak flow rate, than by teat canal length.

Economic importance The disease is of major economic importance in milk production. In individual cows, the loss of production associated with S. agalactiae mastitis is about 25% during the infected lactation, and in affected herds the loss may be of the order of 10–15% of the potential production. Reduction of the productive life represents an average loss of one lactation per cow in an affected herd. Deaths due to S. agalactiae infection rarely if ever occur and complete loss of productivity of a quarter is uncommon, the losses being incurred in the less dramatic but no less important fashion of decreased production per cow.

PATHOGENESIS When the primary barrier of the streak canal is passed, if bacteria are not flushed out by the physical act of milking they proliferate and invasion of the udder tissue follows. There is considerable variation between cows in the developments that occur at each of the three stages of invasion, infection and inflammation. The reasons for this variation are not clear but resistance appears to depend largely on the integrity of the lining of the teat canal. After the introduction of infection into the teat, the invasion, if it occurs, takes 1–4 days and the appearance of inflammation 3–5 days. Again there is much variation between cows in the response to tissue invasion, and a balance may be set up between the virulence of the organism and undefined defense mechanisms of the host so that very little clinically detectable inflammation may develop despite the persistence of a permanent bacterial flora.

The development of mastitis associated with S. agalactiae is essentially a process of invasion and inflammation of lobules of mammary tissue in a series of crises, particularly during the first month after infection, each crisis developing in the same general pattern. Initially there is a rapid multiplication of the organism in the lactiferous ducts, followed by passage of the bacteria through the duct walls into lymphatic vessels and to the super¬mammary lymph nodes, and an out¬pouring of neutrophils into the milk ducts. At this stage of initial tissue invasion,
a short lived systemic reaction occurs and the milk yield falls sharply as a result of inhibition and stasis of secretion caused by damage to acinar and ductal epithelium. Fibrosis of the interalveolar tissue and involution of acini result even though the tissue invasion is quickly cleared. Subsequently, similar crises develop and more lobules are affected in the same way, resulting in a stepwise loss of secretory function with increasing fibrosis of the quarter and eventual atrophy.

The clinicopathological findings vary with the stage of development of the disease. Bacterial counts in the milk are high in the early stages but fall when the SCC rises at the same time as swelling of the quarter becomes apparent. In some cases bacteria are not detectable culturally at this acute stage. The SCC rises by 10–100 times normal during the first 2 days after infection and returns to normal over the next 10 days. The febrile reaction is often sufficiently mild and shortlived to escape notice. When the inflammatory changes in the epithelial lining of the acini and ducts begin to subside, the shedding of the lining results in the clinical appearance of clots in the milk. Thus the major damage has already been done when clots are first observed. At the stage of acute swelling, it is the combination of inflamed interalveolar tissue and retained secretion in distended alveoli that causes the swelling. Removal of the retained secretion at this stage may considerably reduce the swelling and permit better diffusion of drugs infused into the quarter. Inflammatory reactions also occur in the teat wall of affected quarters.

The variations in resistance between cows and the increased susceptibility with advancing age are unexplained. Hormonal changes and hypersensitivity of mammary tissue to streptococcal protein have both been advanced as possible causes of the latter. Local immunity of mammary tissue after an attack probably does not occur but there is some evidence to suggest that a low degree of general immunity may develop. The rapid disappearance of the infection in a small proportion of cows in contrast to the recurrent crises that are the normal pattern of development suggests that immunity does develop in some animals. The antibodies are hyaluronidase inhibitors and are markedly specific for specific strains of the organism. A non-specific rise in other antibodies may occur simultaneously and this is thought to account for the field observations that coincident streptococcal and staphylococcal infections are unusual and that the elimination of one infection may lead to an increased incidence of the other.

**CLINICAL FINDINGS**

In the experimentally produced disease, there is initially a sudden episode of acute mastitis, accompanied by a transient fever, followed at intervals by similar attacks, which are usually less severe. In natural cases fever, lasting for a day or two, is occasionally observed with the initial attack but the inflammation of the gland persists and the subsequent crises are usually of a relatively mild nature. These degrees of severity may be classified as abnormal cow when the animal is febrile and off its feed, abnormal gland when the gland is not greatly swollen, pain and heat are absent and the presence of clots in watery foremilk may be the only apparent abnormality. Induration is most readily palpable at the udder cistern and in the lower part of the udder, and varies in degree with the stage of development of the disease.

The milk yield of affected glands is markedly reduced during each crisis but, with proper treatment administered early, the yield may return to almost normal. Even without treatment the appearance of the milk soon becomes normal but the yield is significantly reduced and subsequent crises are likely to reduce it further.

**CLINICAL PATHOLOGY**

The CAMP test, which has served as the universally used means of identifying *S. agalactiae* for many years, has been displaced by a commercial latex agglutination test, which contains specific reagents necessary for the identification of *S. agalactiae* and is suitable for general laboratory use. 1 When used on isolates of samples from bulk tank milk, the sensitivity and specificity are 97.6% and 98.2%, respectively. An ELISA test correlates well with the bulk tank milk SCC and provides a suitable alternative. 1

The critical judgment to be made is deciding when the quarter infection rate is so high that control or eradication measures are necessary. A decision can be made on the basis of the bulk tank milk SCC as an indicator of the prevalence of mastitis on a quarter basis, and on culture of the bulk tank milk sample to indicate that *S. agalactiae* is the important pathogen, but this approach is too inaccurate to be recommended. There seems to be no alternative to carrying out bacteriological culture and determining SCC on milk samples from individual cows or quarters. Milk samples collected for bacteriological examination for the presence of *S. agalactiae* can be stored in the frozen state. The number of samples that will be culturally positive when the stored frozen samples are thawed will either be unchanged or enhanced up to 200%; the latter response is attributing to fracturing of cellular debris containing *S. agalactiae*.

**Culture from bulk tank milk samples**

The presence of the organism in bulk tank milk is due to shedding of bacteria from infected quarters, with cyclic shedding being typical. The specificity of culture from bulk tank milk is very high; the sensitivity is much lower but can be increased by using selective media.

**Total bacterial count**

The total bacterial count in bulk tank milk can be markedly increased due to the presence of *S. agalactiae* mastitis in the herd. Samples of bulk tank milk from infected herds commonly contain bacterial counts in the range of 20 000–100 000 cfu/mL, because a cow in the early stages of infection can shed up to 100 000 000 bacteria/mL. The standard plate count can drop from 100 000 to 2000 cfu/mL after implementation of a modified blitz therapy and control program to control *S. agalactiae*.

**Culture from individual cow samples**

Composite milk samples are satisfactory, as the number of cows identified as positive does not increase by quarter sampling. 1 The sensitivity and specificity of a single culture from individual cows ranges between 95% and 100%. 1

**Somatic cell count**

*S. agalactiae* produces high SCC in individual cows, which has a significant influence on the bulk tank milk SCC.

**NECROPSY FINDINGS**

The gross and microscopic pathology of mastitis associated with *S. agalactiae* are not of importance in the diagnosis of the disease.

**DIFFERENTIAL DIAGNOSIS**

The clinical diagnosis of *S. agalactiae* mastitis depends entirely on the isolation of *S. agalactiae* from the milk. Differentiation from other types of acute and chronic mastitis is not possible clinically.

**TREATMENT**

*S. agalactiae* is very sensitive to intramammary therapy using a wide variety of commercially available intramammary infusion preparations. Systemic therapy is also effective but offers no advantages over the intramammary route. Clinical cases should be treated whenever they occur because of the need to prevent transmission to uninfected quarters and cows. Subclinical cases identified at any stage of lactation should be treated...
Mastitis of cattle associated with common contagious pathogens

Subclinical S. agalactiae mastitis in New York, all commercially available intramammary infusions were more effective than untreated controls (27% bacteriological cure), with the following bacteriological cure rates: amoxicillin (86%), erythromycin (81%), cloxacillin (77%), cephalixin (66%), penicillin (63%), hetacillin (62%), pirlimycin (44%).

In dry cows, one infusion is sufficient, milk levels of penicillin remaining high for 72 hours. Cloxacillin eliminated the organism from 98% and 100% of infected cows in two different studies.

Blitz therapy
The prevalence of subclinical mastitis due to S. agalactiae can be reduced more rapidly by treatment of infected cows during lactation than by dry cow therapy and postmilking teat dipping. S. agalactiae is one of the few pathogens causing subclinical mastitis that can be treated economically during lactation, and can be eliminated from herds with blitz antimicrobial therapy followed by good sanitation procedures. All cows are sampled and those that are positive are retreated or culled. Failure to institute sanitation procedures for the control of the pathogen may result in subsequent outbreaks of mastitis.

If blitz therapy of all infected cows is not possible because of the short-term effect of lost milk production on income, a modified treatment protocol is recommended. The herd is divided into two groups, based on a composite milk SCC of 500,000. Those cows in the high category are treated with 300 mg of erythromycin, intramammary. When lactating cow numbers reach their lowest point, all animals are treated with the same product. At drying off, cows are treated with 500 mg cloxacillin and 250 mg ampicillin.

CONTROL
Eradication on a herd basis of mastitis associated with S. agalactiae is an accepted procedure and has been undertaken on an area scale in some countries. The control measures as outlined later in this chapter are designed especially for this disease and should be adopted in detail. If suitable hygienic barriers against infection can be introduced and if the infection can be eliminated from individual quarters by treatment, the disease is eradicable fairly simply and economically.

The control program consists of:
- Identifying infected quarters
- Treating infected quarters on two occasions if necessary
- Culling incurable cows.

The control program is particularly applicable in herds where an unacceptable level of clinical cases is backed by a high incidence of subclinical infections. Premilking teat and udder sanitation, postmilking teat dipping, and dry cow therapy are vital aspects of the control program.

Vaccination
Vaccination against S. agalactiae has been attempted and elicits systemic hyperimmunity but no apparent intramammary resistance. Development of an effective vaccine will be difficult because of the multiplicity of strains involved and the known variability between animals in their reaction to intramammary infection.

Biosecurity
As with any eradication program a high degree of vigilance is required to maintain a 'clean' status. This is particularly so with mastitis due to S. agalactiae. Breakdowns are usually due to the introduction of infected animals, even heifers that have not yet calved, or the employment of milkers who carry infection with them. Most dairy farms in the USA are in an ongoing process of herd expansion or replacement acquisition by the addition of purchased animals. Introduction of contagious mastitis associated with S. agalactiae, S. aureus and M. bovis is a common result. It has been recommended that herd additions should be screened for these important pathogens; however, currently available screening tests do not have perfect sensitivity.

MYCOPLASMA BOVIS AND OTHER MYCOPLASMA SPECIES

ETIOLOGY
A number of species of Mycoplasma, especially M. bovis and occasionally Mycoplasma species group 7, Mycoplasma F-38, Mycoplasma argini, Mycoplasma boviris, Mycoplasma canadensis, Mycoplasma bovisgalactitis, Mycoplasma calvescens, Mycoplasma capricolum, Mycoplasma californiae and Mycoplasma dispar, have been isolated from clinical cases. Other mycoplasmas, not usually...
EPIDEMIOLOGY

Occurrence and prevalence of infection
The disease has been recorded since the mid 1960s in the USA, Canada, UK, and Israel and has been observed in Australia. The quarter infection rate in infected herds varies widely.

Source of infection
The epidemiology of the disease has been incompletely characterized. Mycoplasma mastitis occurs most commonly in large herds and in herds where milking hygiene is poor and when cows are brought in from other farms or from public saleyards. Mycoplasma mastitis usually breaks out subsequently after a delay of weeks or even months. The delay in development of an outbreak may be related to the long-term persistence of the organism (more than 12 months) in some quarters, and some cows become shedders of the organism without ever exhibiting signs of severe clinical mastitis. M. bovis was isolated from milk samples of 5–12% of cows during two lactations and two dry periods.

M. bovis is capable of colonizing and surviving in the upper respiratory tract and the vagina, and extramammary colonization explains many of its epidemiological paradoxes. An interesting epidemiological observation is the detection of mycoplasmas and infectious bovine rhinotracheitis virus in infected udders at the same time. The virus could be the much sought-after unknown factor in the etiology of the disease. Outbreaks of mastitis are recorded concurrently with outbreaks of vaginitis and otitis media/ interna vestibulitis.

Transmission
Entry of the disease to a herd is usually by the purchase of animals and their introduction without quarantine. Transmission within a herd is most commonly at milking via machine milking or the hands of milkers. Transmission can also be through the use of bulk mastitis treatments administered through a common syringe and cannula. Although the disease occurs first in the inoculated quarter there is usually rapid spread to all other quarters.

Hematogenous spread of M. bovis has been demonstrated. Colonization of body sites other than the mammary gland is common, and M. bovis isolates from the respiratory and urogenital systems are frequently the same M. bovis subtypes that cause mastitis.

Mycoplasma spp. group 7 has also been isolated from cases of pneumonia and polyarthritis in calves fed milk from cows with mycoplasmal mastitis.

Risk factors
Cows of all ages and at any stage of lactation are affected, cows that have recently calved showing the most severe signs and dry cows the least. There are several recorded outbreaks in dairy herds in dry cows, one of them immediately after mammary infusions of dry period treatment that affected all quarters of all cows.

Experimental production of the disease with M. bovis causes severe loss of milk production, a positive CMT reaction and clots in the milk. Experimental infection produces little tissue necrosis but Mycoplasma are detectable in many tissues, including blood, vagina, and uterus, indicating that hematogenous spread has occurred. It is also apparent that spread of infection between quarters in one cow can be hematogenous. There are no significant pathological differences between mastitis produced by M. bovis genitalium and M. bovis; however, M. bovis remains the most common cause of mycoplasmal mastitis in dairy cattle.

Economic importance
The disease is a disastrous one because of the high incidence in affected herds and the almost complete cessation of production for the lactation. Many cows fail ever to return to milking; as many as 75% of affected cows may have to be culled.

PATHOGENESIS
This is a purulent interstitial mastitis. Although infection probably occurs via the streak canal, the rapid spread of the disease to other quarters of the udder and occasionally to joints suggests that hematogenous spread may occur. The presence of Mycoplasma in heifers milked for the first time also suggests that systemic invasion may be followed by localization in the udder.

CLINICAL FINDINGS
In lactating cows, there is a sudden onset of swelling of the udder, a sharp drop in milk production and grossly abnormal secretion in one or more quarters. In most cases all four quarters are affected and a high-producing cow may fall in yield to almost nil between one milking and the next. Dry cows show little swelling of the udder. Although there is no overt evidence of systemic illness, and febrile reactions are not observed in most field cases in lactating cows, those that have recently calved show most obvious swelling of the udder and may be off their feed and have a mild fever. However, cows infected experimentally show fever up to 41°C (105.5°F) on the third or fourth day after inoculation, at the same time as the udder changes appear. The temperature returns
to normal in 24–96 hours. In some cases the supramammary lymph nodes are greatly enlarged. The classic clinical presentation is severe clinical mastitis in multiple quarters of multiple cows with minimal systemic signs of disease. A few cows, with or without mastitis, develop arthritis in the knees and fetlocks. The affected joints are swollen, with the swelling extending up and down the leg. Lameness may be so severe that the foot is not put to the ground. Mycoplasma may be present in the joint.

The secretion from affected quarters is deceptive in the early stages in that it appears fairly normal at collection; on standing, however, a deposit, which may be in the form of fine, sandy material, flakes or floccules, settles out leaving a turbid whey-like supernatant. Subsequently the secretion becomes scanty and resembles colostrum or soft cheese curd in thin serum. The secretion may be tinged pink with blood or show a gray or brown discoloration. Within a few days the secretion is frankly purulent or curdy but there is an absence of large, firm clots. This abnormal secretion persists for weeks or even months.

Affected quarters are grossly swollen. Response to treatment is very poor and the swollen udders become grossly atrophied. In infection with one strain of the Mycoplasma, many cows do not subsequently come back into production although some may produce moderately well at the next lactation. With other strains there is clinical recovery in 1–4 weeks without apparent residual damage to the quarter.

Mycoplasmal mastitis due to M. bovis genitalium may be very mild and disappear from the herd spontaneously and without causing loss of milk production.17

CLINICAL PATHOLOGY

The causative organism can be cultured without great difficulty by a laboratory skilled in working with Mycoplasma. Samples for culture should be freshly collected and transported at 4°C, and concurrent infection with other bacteria is common. Diagnosis at the herd level can be made by culturing bulk tank milk or milk from cows with clinical mastitis or increased SCC. However, the sensitivity of bulk tank milk culturing is poor (33–59%).18,19 A marked leukopenia, with counts as low as 1800–2500 cells/μL, is present when clinical signs appear and persists for up to 2 weeks. Somatic cell counts in the milk are very high, usually over 20,000,000 cells/mL. In the acute stages the organisms may be able to be visualized by the examination of a milk film stained with Giemsa or Wright-Leishman stain. Species identification of Mycoplasma isolates is most commonly done using immunofluorescence and homologous fluorescein-conjugated antibody or an indirect immunoperoxidase test (immunohistochemistry). Speciation of the causative Mycoplasma species is recommended.

NECROPSY FINDINGS

Grossly, diffuse fibrosis and granulomatous lesions containing pus are present in the mammary tissue. The lining of the milk ducts and the teat sinus is thick and roughened. On histological examination the granulomatous nature of the lesions is evident. Metastatic pulmonary lesions have been found in a few long-standing cases.

Samples for confirmation of diagnosis

- Mycoplasmology – chilled mammary tissue, regional lymph node (special media)
- Histology – fixed mammary tissue.

DIFFERENTIAL DIAGNOSIS

A presumptive diagnosis can be made based on the clinical findings, but laboratory confirmation by culture of the organism is desirable. The facts that the organism does not grow on standard media and that other pathogenic bacteria are commonly present often lead to errors in the laboratory diagnosis unless attention is drawn to the characteristic field findings.

TREATMENT

The majority of M. bovis strains isolated from cattle are susceptible in vitro to fluoroquinolones, florfenicol and tiamulin.20 Approximately half of the isolates are susceptible to spectinomycin, tilmicosin, ceftiofur, ampicillin, or erythromycin.20-21 The clinical relevance of treating mycoplasmal mastitis remains questionable.

Cows diagnosed with mycoplasmal mastitis should be considered to be infected for life. None of the commonly used antimicrobial agents appear to be effective and all–water emulsions used as intramammary infusions appear to increase the severity of the disease. Parenteral treatment with oxytetracycline (5 g intravenously, daily for 3 days) has been shown to cause only temporary improvement. A mixture of tylosin 500 mg and tetracycline 450 mg used as an infusion cured some quarters.22 Unless treatment is administered very early in the course of the disease, the tissue damage has already been done.

CONTROL

Prevention of introduction of the disease into a herd appears to depend upon avoidance of introductions, or isolating introduced cows until they can be checked for mastitis. A popular biosecurity recommendation is to culture the milk of all replacement cows for M. bovis, but the sensitivity and specificity of milk culture in cows with subclinical infections appears to be low. The disease spreads rapidly in a herd and affected animals should be culled immediately or placed in strict isolation until sale. Eradication of the disease can be achieved by culling infected cows identified by culture of milk and nasal swabs, especially at drying off and calving. When eradication is completed the bulk tank milk SCC is the best single monitoring device to guard against reinfection. An alternative program recommended for large herds is the creation of an infected subherd that is milked last. There appears to be merit in the frequent culturing of bulk milk samples as a surveillance strategy for problem herds and areas.

Intramammary infusions must be carried out with great attention to hygiene and preferably with individual tubes rather than multidose syringes. Most commercial teat dips are effective in control. Use of disposable latex gloves with disinfection of the gloved hands between cows may minimize transmission at milking.

Vaccination is a possible development but is unlikely to be a satisfactory control measure because the observed resistance of a quarter to infection after a natural clinical episode is less than 1 year. A M. bovis bacterin is commercially available in the USA that contains multiple strains of M. bovis. Autogenous bacterins have also been made for specific herds; however, no vaccine has proven efficacy for preventing, decreasing the incidence of, or decreasing the severity of clinical signs of mycoplasmal bovine mastitis.24

Mycoplasma are sensitive to drying and osmotic changes, but more resistant than bacteria to the effects of freezing or thawing. Amputating the teats of affected quarters may result in heavy contamination of the environment and is not recommended. Because M. bovis can cause respiratory disease, otitis media/interna and arthritis in calves, all colostrum and waste milk fed to calves should be pasteurized.
Mastitis of cattle associated with teat skin opportunistic pathogens

**COAGULASE-NEGATIVE STAPHYLOCOCCI**

Because of the intense investigation of coagulase-positive staphylococcal mastitis (S. aureus), coagulase-negative staphylococcal intramammary infections have become under closer scrutiny and are now among the most common bacteria found in milk, especially in herds in which the major pathogens have been adequately controlled. There is considerable debate about the significance of these pathogens for the mammary gland and for cow productivity. For this reason, these pathogens are classified as minor pathogens.

**ETIOLOGY**

Coagulase-negative staphylococci are commonly but minor contagious pathogens that include *Staphylococcus epidermidis, S. hyicus, S. chromogenes, S. simulans,* and *Staphylococcus warneri.* Staphylococci that are normal teat skin flora, and *Staphylococcus xylosus* and *Staphylococcus scirr* that come from an uncertain site.

**EPIDEMIOLOGY**

Coagulase-negative staphylococci are teat skin opportunistic pathogens and cause mastitis by ascending infection via the streak canal. Coagulase-negative staphylococcal infections appear to have a protective effect against colonization of the teat duct and teat skin by *S. aureus* and other major pathogens, with the exception of *E. coli* and the environmental streptococci. Studies in the US found that 20–70% of heifer quarters are affected before parturition with coagulate-negative staphylococci, but these infections are usually eliminated spontaneously or with antimicrobial therapy during early lactation. A survey of the prevalence and duration of intramammary infection in heifers in Denmark in the periparturient period found *S. chromogenes* in 15% of all quarters before parturition, but this decreased to 1% of all quarters shortly after parturition. In Finland, coagulase-negative staphylococci are the most commonly isolated bacteria from milk samples of heifers with mastitis. Infections with *S. simulans* and *S. epidermidis* occurred in 1–3% of quarters both before and after parturition. Infection with *S. simulans* persisted in the same quarter for several weeks, but intramammary infections with *S. epidermidis* were transient. Coagulase-positive *S. hyicus* and *Staphylococcus intermedius* have been isolated from some dairy herds and can cause chronic, low-grade intramammary infections.

The prevalence of *S. aureus* was 0.9% in parturient and postpartum dry cows, and it was 2.2% in chronic dry cows and dairy cows. In a dairy herd in Wisconsin, the prevalence of *S. aureus* was 23% in prepartum quarter infections and 6.8% in postpartum quarter infections.

**TREATMENT**

Spontaneous resolution is common in *S. choleraesuis* infections. Some cases of *S. anserina* and *S. warneri* are usually cured spontaneously or with antimicrobial therapy during early lactation.

**CONTROL**

The implementation of intramammary therapeutic programs that control these opportunistic pathogens is not indicated.

**REFERENCES**

Mastitis of cattle associated with common environmental pathogens

**Clinical findings**

Acute - swelling of gland, watery milk with small flakes, mild systemic response, recovery in few days.

Peracute - sudden onset of severe toxemia, fever, tachycardia, impending shock; cow may be recumbent. Quarter may or may not be swollen and warm, secretions thin and serous and contain very small flakes. May die in few days.

**Clinical pathology**

Culture milk. Somatic cell count. Marked leukopenia, neutropenia and degenerative left shift. Bacteremia may occur, particularly in severely affected cattle.

**Necropsy findings**

Edema, hyperemia, hemorrhages and necrosis of mammary tissue. Major changes in teat and lactiferous sinuses and ducts; invasion of organism into parenchyma not a feature of E. coli.

**Diagnostic confirmation**

Culture of organism from milk and high SCC.

**Differential diagnosis**

- Parturient hypocalcemia paresis
- Carbohydrate engorgement lactic acidosis

Other causes of acute and severe mastitis (must culture milk):

- Environmental streptococci
- S. aureus and S. agalactiae

**Treatment**

Must consider status and requirements for each case based on severity. Use of antimicrobial agents is indicated in moderately to severely affected animals; efficacy uncertain in mild cases. Some infections become persistent if antibiotics are not administered. Severely affected cattle also need supportive fluid and electrolyte therapy (such as hypertonic saline), and possibly NSAIDs for endotoxemia.

**Control**

Manage outbreaks by examination of environment. Improve sanitation and hygiene. Regular cleaning of bedding. Emphasize premilking hygiene, including premilking germicide teat dipping and keep cows standing for at least 30 minutes after milking. Core lipopolysaccharide antigen vaccine in dry cows on pasture if possible. Replace sawdust and shavings with sand for bedding. Emphasize premilking hygiene, including premilking germicide teat dipping and keep cows standing for at least 30 minutes after milking. Core lipopolysaccharide antigen vaccine in dry cows on pasture if possible. Replace sawdust and shavings with sand for bedding.

**Synopsis**

**Etiology**

Many different serotypes of E. coli, numerous capsular types of Klebsiella spp. and Enterobacter aerogenes.

**Epidemiology**

Dairy cattle housed in total confinement or drylot; uncommon in pastured cattle. Most important mastitis problem in well managed, low-SCC herds. Quarter infection rate low at 2-4%. Incidence highest in early lactation. 80-90% of coliform infections result in clinical mastitis; 8-10% are peracute. Causes clinical mastitis rather than subclinical mastitis. Source of infection is environment between milkings, during dry period and prepartum in heifers. Isolates of E. coli are opportunists. Sawdust and shavings bedding contaminated with E. coli and Klebsiella spp. (particularly K. pneumoniae) major source of bacteria; much worse when wet (rainfall or high humidity). Coliform intramammary infection highest during 2 weeks following drying off and in 2 weeks prior to calving. Animal risk factors include:

- Low SCC
- Decrease of neutrophil function in periparturient cow
- High susceptibility in early lactation
- Contamination of teat duct
- Selenium and vitamin E status.

**Control**

Implementation of a mastitis control program will be very effective in decreasing intramammary infection due to coagulase-negative staphylococci. Because of its status as a minor pathogen, specific control measures (such as vaccination) are not indicated.

**REFERENCES**

The occurrence of coliform mastitis has with clinical mastitis rather than subclinical winter or summer months. Where cows during wet, heavy rainfall seasons. The lactation. The rate of infection is also increased considerably in recent years industry and amongst dairy practitioners. Coliform mastitis occurs worldwide and is a major concern in dairy industry and amongst dairy practitioners. Clinical mastitis associated with environmental mastitis associated with environmental pathogens (including the environmental streptococci) is now the most important mastitis problem in well managed, low-SCC herds. In a survey of the incidence of clinical mastitis and distribution of pathogens in dairy herds in the Netherlands, the average annual incidence was 12.7 quarter cases per 100 cows per year. The most frequent isolates from clinical cases were E. coli (16.9%), S. aureus (14.4%), S. uberis (11.9%) and S. dyelaactae (8.9%).

The incidence of clinical coliform mastitis is highest early in lactation and decreases progressively as lactation advances. The rate of intramammary infection is around 10 times greater during the dry period than during lactation. The rate of infection is also higher during the first 2 weeks of the dry period and during the 2 weeks before calving. 80–90% of coliform infections results in varying degrees of clinical mastitis in the lactating cow; approximately 5–10% of coliform infections result in peracutis mastitis, usually within a few days after calving. The disease also occurs commonly in heifers that concentrate calving over a short period of time.

Prevalence of infection
The prevalence of both intramammary infection and the incidence of clinical mastitis due to coliform bacteria has increased, particularly in dairy herds with a low prevalence of infection and incidence of clinical mastitis due to S. aureus and S. agalactiae as a result of an effective mastitis control program. Compared to other cases of mastitis, coliform infections are relatively uncommon and, in data based on herd surveys, the percentage of quarters infected with these pathogens is low. The percentage of quarters infected at any one time is generally low, at about 2–4%.

In the UK, about 0.2% of quarters of cows may be infected at any one time. Surveillance of a dairy herd in total confinement in the USA indicated that infection with coliform bacteria by either day of lactation or day of the year never exceeded 3.5% of quarters, and this maximum was reached on the day of calving. However, coliform infections may cause 30–40% of clinical mastitis episodes. In herds with a problem, up to 8% of cows have been infected with coliform bacteria, and 80% of the cases of clinical mastitis may be due to coliform infections.

Duration of infection
Coliform intramammary infections are usually of short duration. Over 50% last less than 10 days; about 70% less than 30 days; and only 1.5% exceed 100 days in duration.

Source of infection and mode of transmission
The primary reservoir of coliform infection is the dairy cow’s environment (environmental pathogen); this is in contrast to the infected mammary gland, which is the reservoir of major contagious pathogens (S. aureus and S. agalactiae) and the main reservoir of infection in cattle with M. bovis. Exposure of uninfected quarters to environmental pathogens can occur at any time during the life of the cow, including during milking, between milkings, during the dry period and before calving in heifers.

Morbidity and case fatality
In dairy herds with low bulk tank milk SCCs the average herd incidence of clinical mastitis is 45–50 cases per 100 cows annually, while coliforms isolated from 30–40% of the clinical cases. This is similar to an average incidence of 15–20 cases of coliform mastitis per 100 cows in herds with low bulk tank milk SCCs. Other observations indicate that the number of clinical cases of coliform mastitis varies from 3 to 20 per 100 cows per year but the average incidence in dairy herds can be as low as 6–8 per 100 cows per year.

Coliform mastitis is one of the most common causes of fatal mastitis in cattle. The case fatality rate from peracute coliform mastitis is commonly high and may reach 80% in spite of intensive therapy. Outbreaks of the disease can occur with up to 25% of recently calved cows affected within a few weeks of each other.

Risk factors
Pathogen risk factors
The isolates of E. coli from bovine mastitic milk are simply opportunist pathogens. The isolates that cause coliform mastitis possess lipopoly saccharides (endotoxin), which form part of the outer layer of the cell wall of all Gram-negative bacteria. Coliform bacteria isolated from the milk of cows or from their environment have different degrees of susceptibility to the bactericidal action of bovine sera, with almost all the isolates that cause severe mastitis being serum-resistant. Serum-sensitive organisms are unable to multiply in normal glands because of the activity of bactericidins reaching milk from the blood. Of the strains of E. coli isolated from cases of mastitis in cattle in England and Wales, only those that were serum-resistant were re-isolated from expressed milk following intramammary inoculation of lactating cows. Other observations indicate that serum-resistant coliforms have no selective advantage over serum-susceptible coliforms in naturally occurring intramammary infections. There are also somatic and capsular factors of coliforms that affect resistance to bovine bactericidal activity. Strains of Klebsiella that cause mastitis are also resistant to bovine serum. The fibronectin binding property of E. coli from bovine mastitis may be an important virulence factor that allows the organism to adhere to the ductal epithelium.

Environmental risk factors
All the environmental components that come in contact with the udder of the cow are considered potential sources of the organisms. The coliform bacteria are opportunists, and contamination of the skin of the udder and teats occurs primarily between milkings when the cow is in contact with contaminated bedding rather than at the time of milking. Feces, which are a common source of E. coli, can contaminate the perineum and the udder directly or indirectly through bedding, calving stalls, dairy yard, teat cups and milkers’ hands. Cows with chronic coliform mastitis also provide an important source of bacteria, and direct transmission probably occurs through the milking machine. Inadequate drying of the base of the udder and the teats after washing milk to prevent contamination with water can lead to a drainage of coliform-contaminated water down into the teat cups and subsequent infection.

Bedding
Sawdust and shavings used as bedding that are contaminated and harbor E. coli, and particularly K. pneumoniae, are major risk factors for coliform mastitis. Cows bedded on sawdust have the largest teat end population of total coliforms and klebsiellas; those bedded on shavings have an intermediate number and those
on straw have the least. Experimentally, the incubation of bedding samples at 30–44°C (86–111°F) resulted in an increase in the coliform count; at 22°C (71°F) the count was maintained, and at 50°C (122°F) the bacteria were killed. Wet bedding, particularly sawdust and shavings, promotes the growth of coliform bacteria, especially Klebsiella spp. The relationship between the bedding populations of Enterobacteriaceae was studied over a 12-month period in a dairy herd. The analyses revealed that rainfall helped the bedding populations of E. coli and coliform mastitis incidence were statistically independent, while there was a strong association between rainfall and K. pneumoniae bedding populations and the incidence of K. pneumoniae mastitis. The lack of an association between bedding population of E. coli and coliform mastitis, along with the observation that cows are most susceptible immediately after parturition, suggest that the ability of the bacteria to penetrate the steth canal may be a factor of resistance in the cow and not a characteristic of the organism. Also, it appears that the cow in early lactation is not as susceptible to K. pneumoniae as to E. coli.

The ability of several different bedding materials to support the growth of environmental pathogens has been outlined under controlled conditions. Bedding materials vary in their ability to support growth of different pathogens, and under barn conditions it appears that high bacterial counts are influenced by factors more complex than type of bedding alone. Even clean damp bedding may support bacterial growth. High populations of coliform bacteria on the teat end, unless accompanied by actual chronic quarter infection, are probably transitory and represent recent environmental contamination that would usually be eliminated by an effective sanitation program at milking time. However, any teat skin population, whether associated with infection in another quarter, from contaminated teat cup liners or from other environmental sources, must be considered as a potential source of new infection.

Animal risk factors
Factors that influence the susceptibility of cows to coliform mastitis include the SCC of the milk, the stage of lactation and the physiological characteristics and defense mechanisms of the udder (particularly the speed of neutrophil recruitment), teat characteristics, and the ability of the cow to counteract the effects of the endotoxins elaborated by the organisms.

Somatic cell count
Experimentally, an SCC of 250,000 cells/mL in the milk of a quarter may limit significant growth of bacteria and development of mastitis when small inocula of coliform organisms are experimentally introduced into the gland. Somatic cell counts of 500,000 cells/mL provided complete protection. Thus cows in herds with a low incidence of streptococcal and staphylococcal mastitis have a low milk SCC and are more susceptible to coliform mastitis. Dairy herds with low herd bulk tank milk SCCs may have a greater incidence of severe toxic mastitis than herds with higher counts.

Neutrophil recruitment and function
Increased susceptibility to coliform mastitis in the periparturient cow is primarily due to impaired neutrophil recruitment to the infected gland. In fatal cases of peracute mastitis in cows within 1 week after parturition there may be large numbers of bacteria in mammary tissues and an absence of neutrophil infiltration. Other observations indicate a high correlation between poor preinfection chemotactic activity of blood neutrophils and susceptibility to intramammary E. coli challenge exposure. Experimentally, in periparturient cows the inability to recruit neutrophils rapidly into the mammary gland following intramammary infection is associated with an overwhelming bacterial infection and peracute highly fatal mastitis. The periparturient cows are unable to control bacterial growth during the first few hours after bacterial inoculation and consequently the bacterial load is much higher when neutrophils finally enter the milk. The lack of neutrophil mobilization could be due to:
- Failure to recognize bacteria
- Lack of production of inflammatory mediators
- A defect in the ability of the cells to move into the milk compartment.

In ketonemic cows, experimental E. coli mastitis is severe, regardless of preinfection chemotactic response.

High levels of cytokines are present in the milk of cows that lack the ability to recruit leukocytes, which is evidence that the cells recognized the bacteria. All of this suggests that the critical defect is in the neutrophils of the periparturient cow. Certain cell-surface receptors on leukocytes may be important defense mechanisms against E. coli polysaccharides. Bovine mammary neutrophils possess cell-surface C14 and C18 and lectin-carbohydrate interactions mediating non-opsonic phagocytosis of E. coli, which may be important in controlling these infections.

Selenium and vitamin E status
The positive effects of supplemental vitamin E and selenium on mammary gland health are well established. An adequate dietary level of selenium enhances the resistance of the bovine mammary gland to infectious agents. Experimentally induced intramammary E. coli infections are significantly more severe, and of longer duration, in cows whose diets have been deficient in selenium than in cows whose diets were supplemented with selenium. The enhanced resistance is thought to be associated with a more rapid diapedesis of neutrophils into the gland of cows fed diets supplemented with selenium, which limits the numbers of bacteria in the gland during infection.

Vitamin E is especially important to mammary gland health during the peripartum period. Plasma concentrations of alpha-tocopherol begin to decline at 7–10 days before parturition, reach nadir at 3–5 days after calving and then start increasing. When plasma concentrations are maintained during the peripartum period by injections of alpha-tocopherol, the killing ability of blood neutrophils is improved. The supplementation of the diets of dry cows receiving 0.1 ppm of selenium in their diets with vitamin E at 1000 IU/d reduced the incidence of clinical mastitis by 30% compared to cows receiving 100 IU/d. The reduction was 88% when cows were fed 4000 IU/d of vitamin E during the last 14 days of the dry period.

There are also marked effects of dietary selenium on milk eicosanoid concentrations in response to an E. coli infection, which may be associated with the altered pathogenesis and outcome of mastitis in a selenium-deficient state.

Stage of lactation and defense mechanism
Coliform mastitis occurs almost entirely in the lactating cow and rarely in the dry cow. The disease can be produced experimentally in lactating quarters much more readily than in dry quarters. The difference in the susceptibility may be due to the much higher SCCs and lactoferrin concentrations in the secretion of dry quarters than in the milk of lactating quarters. Cows with known uninfected quarters at drying off may develop peracute coliform mastitis at calving, suggesting that infection occurred during the dry period. New intramammary infections can occur during the nonlactating period, especially during the last 30 days, remain latent until parturition and cause peracute mastitis after parturition.

The rate of intramammary infection is highest during the 2 weeks following drying off and in the 2 weeks before calving. The fully involuted mammary gland appears to be highly resistant to experimental challenge by E. coli but it becomes susceptible during the immediate
prepartum period. More than 93% of *E. coli* intramammary infection associated with the nonlactating period originated during the second half of that period.16

Several physiological factors may influence the level of resistance of the nonlactating gland to *E. coli* infection. The rate of new intramammary infection is highest during transitions of the mammary gland from lactation to involution and during the period of colostrum production to lactation. There can be a sixfold increase in coliform infections from late lactation to early involution but only 50% of these new infections do not persist into the next lactation. Also, the rate of spontaneous elimination of minor pathogens is high during the nonlactating period. The difference in susceptibility or resistance to new intramammary infection may be due, in part, to changes in concentration of lactoferrin, IgG, bovine serum albumin and citrate, which are correlated with in vitro growth inhibition of *K. pneumoniae*, *E. coli*, and *S. uberis*.

There is also a slower increase in polymorphonuclear neutrophils in milk after new intramammary infection in early lactation than in mid and late lactation. These conditions may explain the occurrence of peracute *E. coli* mastitis in early lactation. This suggests latent infection or, more likely, that infection occurred at a critical time just a few days before and after calving, when the streak canal became patent and the population of *E. coli* bacteria on the teat end was persistently high because the cow was not being milked routinely and thus would not be subjected to udder washing and teat dipping. Coliform bacteria can pass through the streak canal unaided by machine milking – this may be associated with the high incidence of *E. coli* mastitis in high-yielding older cows, which may have increased patency of the streak canal with age. Newly calved cows can be classified as moderate or severe responders to experimentally induced coliform mastitis. Following infection there is a diversity of responses varying from very mild to very acute inflammation of the gland and evidence of systemic effects such as fever, anorexia and discomfort. Losses in milk yield and compositional changes are most pronounced in inflamed glands and, in severe responders; milk yield and composition did not return to preinfection levels. It is proposed that the severe and long-lasting systemic disturbances in severe responders can be attributed to absorption of endotoxin.

In summary, coliform mastitis is more severe in periparturient cows because of inability to slow bacterial growth early after infection. This inability is associated with low SCC before challenge and slow recruitment of neutrophils,17 there may also be deficits in the ability of leukocytes to kill bacterial pathogens.

**Contamination of teat duct**

The sporadic occurrence of the disease may be associated with the use of contaminated teat siphons and mastitis tubes and infection following traumatic injury to teats or following teat surgery. Several teat factors are important in the epidemiology of *E. coli* mastitis. It is generally accepted that *E. coli* is common in the environment of housed dairy cows and that mastitis can be produced experimentally by the introduction of as few as 20 organisms into the teat cistern via the teat duct. However, the processes by which this occurs under natural conditions are unknown. *E. coli* does not colonize the healthy skin of the udder or the teat duct.

The teat duct normally provides an effective barrier to invasion of the mammary gland by bacteria. As a result of machine milking there is some relaxation of the papillary duct, followed by gradual reduction in the duct lumen diameter in the 2 hours following milking. This period of relaxation after milking may be a risk factor predisposing to new intramammary infection.

Experimental contamination of the teat ends with a high concentration of coliform bacteria by repeated wet contact, however, does not necessarily result in an increase in new intramammary infection. The experimental application of high levels of teat end contamination with *E. coli* after milking repeatedly led to high rates of intramammary infection, which suggests that penetration of the teat duct by *E. coli* occurs in the period between contamination and milking. Milking machines that produce cyclic and irregular vacuum fluctuations during milking can result in impacts of milk against the teat ends, which may propel bacteria through the streak canal and increase the rate of new infections due to *E. coli* and outbreaks of peracute coliform mastitis.

**Downer cows**

Cows affected with the downer cow syndrome following parturient paresis, or recently calved cows that are clinically recumbent for any reason, are susceptible to coliform mastitis because of the gross contamination of the udder and teats with feces and bedding.

**Other defense factors**

**Lactoferrin and citrate**

The failure of lactoferrin within mammary secretions to prevent new infections and mastitis near and after parturition may be due to a decrease in lactoferrin before parturition. Lactoferrin normally binds the iron needed by iron-dependent organisms; these multiply excessively in the absence of lactoferrin. Also, citrate concentrations increase in mammary secretions at parturition and may interfere with iron-binding by lactoferrin.

**Serum antibody to *E. coli***

The serum IgG1 ELISA titers recognizing core lipopolysaccharide antigens of *E. coli* J5 in cattle are associated with a risk of clinical coliform mastitis. Titers less than 1:240 were associated with 53 times the risk of clinical coliform mastitis. Older cattle in the fourth or greater lactations were also at greater risk, even though titers increased with age. There is a tier-independent age-related increase in clinical coliform mastitis. Active immunization of cattle with an Rc-mutant *E. coli* (J5) vaccine resulted in a remarkable decrease in the incidence of clinical coliform mastitis.18

**PATHOGENESIS**

After invasion and infection of the mammary gland, *E. coli* proliferates in large numbers and releases endotoxin on bacterial death or during rapid growth when excess bacterial cell wall is produced. Endotoxin causes a change in vascular permeability, resulting in edema and acute swelling of the gland and a marked increase in the number of neutrophils in the milk.19 The neutrophil concentrations may increase 40–250 times and strongly inhibit the survival of *E. coli*. The marked diapedesis of neutrophils is associated with the remarkable systemic leukopenia and neutropenia that occurs in peracute coliform mastitis. The severity of the disease is influenced by:

- The degree of the pre-existing neutrophil and the milk.
- The rate of invasion and total number of neutrophils that invade the infected gland.
- The susceptibility of the bacteria to serum bactericidins that are secreted into the gland.
- The amount of endotoxin produced.19

**Stage of lactation**

The severity of disease is dependent on the stage of lactation. Experimental infection of the mammary gland of recently calved cows with *E. coli* produces a more severe mastitis when compared with animals in midlactation. This may be due to a delay in diapedesis of neutrophils into the mammary gland of recently calved cows. Furthermore, because of this delay there may be no visible changes in the milk for up to 15 hours after infection, but the systemic effects of the endotoxin released by the bacteria are evident in the cow (fever, tachycardia, anorexia, rumen...
hypomotility or atony, mild diarrhea). The net result is endotoxemia, which persists as long as bacteria are multiplying and releasing endotoxin. This persistent endotoxemia is probably a major cause of failure to respond to therapy compared to the transient endotoxemia in the experimental inoculation of one dose of endotoxin.

**Neutrophil response**

The final outcome is highly dependent on the degree of neutrophil response. If the neutrophil response is delayed and growth of the organism is unrestricted, the high levels of toxin produced could cause severe destruction of udder tissue and general toxemia. If the animal responds quickly there is often little effect on milk yield because the injury is confined to the sinuses without involvement of secretory tissues. The ability of the neutrophils to kill E. coli varies among cows. Experimental infection of the mammary gland of cows with E. coli results in the stimulation of a long-lasting opsonic activity for the phagocytosis and killing of the homologous strain of the organism by neutrophils. Thus it is not opsonic deficiency that is the problem in early lactation but rather a failure of rapid migration of neutrophils into the gland cistern.

The rapidity and efficiency of the neutrophil response are major factors in determining the outcome. If the neutrophil response is rapid, clinical disease will be mild or go undetected, self-cure will occur and the cow returns to normal; the milk may be negative for the bacteria. This may be one important cause of an increase in the percentage of clinical mastitis cases in which no pathogens can be isolated from the milk. Failure of the cow to mount a significant neutrophil response results in the multiplication of large numbers of bacteria, the elaboration of large amounts of endotoxin and severe highly fatal toxemia. In these cases, bacteria are readily cultured from the milk. In less serious and nonfatal cases, the recruitment of neutrophils does not fail but is delayed; this results in acute clinical mastitis with progressive inflammation and permanent loss of secretory function. The bacteria are not always readily eliminated from the infected gland by the neutrophils. Coliform bacteria may remain latent in neutrophils and, in naturally occurring cases, it is not uncommon to be able to culture the organism from the mammary gland during and after both parenteral and intramammary antibacterial therapy.

**Numbers of bacteria in milk**

The numbers of bacteria in the milk also influence the outcome. If bacterial numbers exceed 10^8 cfu/mL, the ability of the neutrophil to phagocytose is impaired. If the bacterial count is less than 10^3 cfu/mL at 12 hours postinfection, the bacteria will be rapidly eliminated and the prognosis will be favorable. This response is seen as a subacute form of the disease with spontaneous self-cure. If the neutrophil response is slow or delayed, the cow will exhibit more severe signs of coliform mastitis due to toxemia. This is most common in recently calved cows and is characterized clinically by a severe infection in the affected quarter that later becomes watery, fever, depression, ruminal hypomotility and mild diarrhea. The prognosis in these cases is unfavorable. These more severe forms of coliform mastitis usually occur after calving and in the first 6 weeks of lactation. Cows with coliform mastitis in mid to late lactation generally generate a rapid neutrophil response rate and their prognosis is likely to be favorable.

**Experimental endotoxin-induced mastitis**

In an attempt to further understand the pathogenesis of coliform mastitis, the effect of experimentally introducing E. coli endotoxin into the mammary gland has been examined. The intramammary infusion of 1 mg E. coli endotoxin induces acute mammary inflammation and transient, severe shock from which cows recover within 48–72 hours. Udder edema is apparent within 2 hours but begins to subside in 4–6 hours. The SCC increases within 3–5 hours and at 7 hours the count is 10 times normal. A mild systemic reaction with a transient fever occurs in some cows. High concentrations of interleukin-1 and interleukin-6 are detectable in the milk of infused glands, beginning 3–4 hours after infusion. Milk concentrations of bovine serum albumin are increased from baseline levels to peak levels within 2 hours, indicating increased vascular permeability induced by inflammatory mediators. The infusion of endotoxin into the teat cistern of cows induces a rapid local inflammatory response of short duration with an influx of neutrophils into the teat cistern.

The intramammary infusion of endotoxin results in a sequential increase of bovine serum albumin, histamine, serotonin, leukotrienes and arachidonic metabolites and is also released following experimental K. pneumoniae mastitis. There is also a marked increase in prostaglandin concentrations, which indicates that they may play a role in the pathogenesis of endotoxin-induced mastitis and that the use of NSAIDs may be of value therapeutically.

In peracute coliform mastitis, severe toxemia with fever, shivering, weakness leading to recumbency in a few hours, and mild diarrhea are common and probably due to the absorption of large quantities of endotoxin. For many years it was thought that bacteremia did not occur in severe cases of coliform mastitis. However, bacteremia is present in 32–48% of naturally occurring cases of coliform mastitis. In experimental endotoxemia in cattle there is profound leukopenia (neutropenia and lymphopenia), a mild hypocalcemia and elevation in plasma cortisol concentration. Hypocalcemia also occurs in naturally occurring cases and is thought to be due to decreased abomasal emptying rate associated with the endotoxemia. Experimentally infused endotoxin is detoxified very rapidly after absorption into the circulation.

In the acute form, the systemic changes are usually less severe than in the peracute form. However, in both forms, there is marked agalactia and the secretions in the affected quarter become serous and contain small flakes. Coliform organisms are not active tissue invaders, and in affected cattle that survive the systemic effects of the endotoxin the affected quarter(s) will usually return to partial production in the same lactation, and even full production in the next. However, in some cows that survive the peracute form, subsequent milk production in the current lactation is inadequate and cows are commonly culled.

A retrospective analysis of cows with clinical and laboratory features of coliform mastitis revealed that 60% returned to produce a milk-like secretion in the affected quarters in the current lactation and 40% did not. However, only 63% of the former group and 14% of the latter group remained in the herd and produced milk in the next lactation. Some cows were culled during the current lactation for low milk production and other reasons, some died and others were culled for mastitis. Of the original 88 cows with coliform mastitis, only 38 (43%) remained in the herd and produced milk in the next lactation.

**Clinical Findings**

Peracute coliform mastitis in the cow is a severe disease characterized by a sudden onset of agalactia and toxemia. The cow
may be normal at one milking and acutely ill at the next. Complete anorexia, severe depression, shivering and trembling, cold extremities (particularly the ears) and a fever of 40–42°C (104–108°F) are common. Within 6–8 hours after the onset of signs the cow may be recumbent and unable to stand. At that stage, the temperature may be normal or subnormal, all of which may superficially resemble parturient paresis. The heart rate is usually increased up to 100–120 beats/min, the rumen is static, there may be a mild watery diarrhea and dehydration is evident. Polyneura is common and in severe cases an expiratory grunt may be audible because of pulmonary congestion and edema.

The affected quarter(s) is usually swollen and warm but not remarkably so, and for this reason coliform mastitis may be missed on initial clinical examination. The cow may be severely toxemic, febrile and have cold extremities before there are visible changes in the mammary gland or the milk. The mammary secretion is characteristic, and changes from the consistency of watery milk initially to a thin, yellow serous fluid containing small meal-like flakes that are barely visible to the naked eye and are best seen on a black strip plate used for gross examination of milk. Additional quarters may become affected within a day or two of the initial infection.

The course of peracute coliform mastitis is rapid. Some cows will die in 6–8 hours after the onset of signs; others will live for 24–48 hours. Those that survive the peracute crisis will either return to normal in a few days or remain weak and recumbent for several days and eventually develop the complications associated with prolonged recumbency. Intensive intravenous fluid therapy may prolong the life of the cow for up to several days but significant improvement may not occur and eventually euthanasia may appear to be the desirable course of action.

Acute coliform mastitis is characterized by varying degrees of swelling of the affected gland and variable systemic signs of fever and inappetence. The secretions of the gland are watery to serous in consistency and contain flakes. Recovery with appropriate treatment usually occurs in a few days.

Accuracy of clinical diagnosis
Various diagnostic schemes that use clinical parameters to differentiate cows with clinical mastitis due to Gram-negative bacteria from those with clinical mastitis associated with Gram-positive bacteria have been developed.28–34 In general, all these schemes predict Gram-negative bacteria as the cause if the milk is watery or yellow, if the mastitis episode occurs in summer and if rumen motility is decreased or absent. Experienced clinicians are not much better at predicting the causative agent than inexperienced clinicians. The conclusion from all of these studies is that clinical observations do not allow sufficiently accurate prediction of clinical mastitis pathogens and should not be used as the sole criteria for deciding whether cows are treated with antibiotics, or even the class of antibiotic to be administered.34 Even the best predictive algorithm was wrong 25% of the time if the prevalence of Gram-negative mastitis was 50%, which is too high an error rate to be used to guide treatment. For comparison, flipping a coin to attribute the causative agent as being Gram-positive or Gram-negative is wrong only 50% of the time.

An increase in the ability of a positive test to predict a Gram-negative bacterial infection as the cause for a clinical mastitis episode is provided by examining for the presence of endotoxin in milk (sensitivity (Se) = 0.72; specificity (Sp) = 0.95), whether the segmented neutrophil count is less than 35% of the total leukocyte count (Se = 0.87; Sp = 0.71),36 whether the segmented neutrophil count is less than 3200 cells/µL (Se = 0.93; Sp = 0.89),36 and by culturing on selective media (Se = 0.60; Sp = 0.98).37 The endotoxin test is a cowside test (Limast-test®) that is commercially available in Scandinavia. The test takes 15 minutes to run on milk samples and is able to detect the presence of endotoxin and therefore Gram-negative bacteria, but does not differentiate between E. coli and K. pneumoniae.

Hematology
In peracute coliform mastitis there is hemocoagulopathy, a marked leukopenia, neutropenia and a degenerative left shift due to the margination of large numbers of neutrophils in response to endotoxin. There is also a moderate lymphopenia, monocytopenia and thrombocytopenia.36 If the degenerative left shift, leukopenia and neutropenia become worse on the second day after the onset of clinical signs, the prognosis is unfavorable. An improvement in the differential white count on the second day is a good prognostic sign.

Endotoxin presence in milk and plasma
A commercially available cowside test (Limast-test®) for endotoxin is available in Scandinavia. The test takes 15 minutes to run on milk samples and is able to detect the presence of endotoxin and therefore Gram-negative bacteria, but does not differentiate between E. coli and K. pneumoniae.

Serum biochemistry
The biochemical abnormalities observed in naturally occurring cases include uremia, high aspartate aminotransferase activity and strong ion (metabolic) acidosis in fatal cases, while in surviving cases there were decreased concentrations of sodium, potassium and chloride, and strong ion (metabolic) alkalosis.25,36

NECROPSY FINDINGS
There is edema and hyperemia of the mammary tissue. In severe cases hemorrhages are present and are accompanied by thrombus formation in the blood and lymphatic vessels; there is necrosis of the parenchyma.

A study of the progressive pathological changes in experimental and natural cases of E. coli mastitis in cows reveals that damage is most marked in the epithelium of the teat and lactiferous sinuses and diminishes rapidly towards the ducts. In hyperacute cases, the organisms are largely confined to the ductular and secretory lumen and there is
little invasion of the parenchyma, despite the presence of large numbers of organisms. In some cases there may be intense neutrophil infiltration, subepithelial edema and epithelial hyperplasia of the sinuses and large ducts. In hyperacute cases in the immediate postpartum period, infiltration of neutrophils may be negligible. There is now some evidence that bacteremia may occur in coliform mastitis.\(^{25}\)

**Samples for confirmation of diagnosis**

- Bacteriology – chilled mammary tissue, regional lymph node
- Histology – formalin-fixed mammary tissue.

### Differential Diagnosis

- **Peracute coliform mastitis**
  - In cattle, it is characterized clinically by a sudden onset of toxemia, weakness, shivering, often recumbency, fever in the early stages followed by a normal temperature or hypothermia in several hours, and characteristic gross changes in the milk, which usually is watery and contains some particles barely visible to the unaided eye. The peracute form of the disease is most common in recently calved cows.
  - **Parturient hypocalcemia paresis** occurs in recently calved cows. The weakness and recumbency resembles peracute coliform mastitis but the marked increase in heart rate, and dehydration and mild diarrhea if present, are not characteristic of parturient paresis and should prompt further clinical examination, particularly of the udder. In the early stages of coliform mastitis the changes in the milk may be just barely visible. Those clinical findings which are most useful in predicting peracute coliform mastitis are the presence of large numbers of organisms, often neutrophils and with varying degrees of success based on antibiotic therapy. The benefit-cost ratio of this extralabel use and the lack of pharmacokinetic data for adequate withholding times, the risk of drug residues in milk and meat is increased.

**TREATMENT**

The treatment of coliform mastitis in cattle has been controversial but recent studies have clarified the important role that antimicrobial agents play in treating severely affected cattle. Historically, the treatment of coliform mastitis was based on the principles of treating a bacterial infection with varying degrees of inflammation. A combination of broad-spectrum antimicrobial agents administered parenterally and by intramammary infusion, fluid and electrolyte therapy, frequent stripping out of the affected glands with the aid of oxytocin, and anti-inflammatory drugs have been used with varying degrees of success based on empirical and anecdotal experience. Only a handful of clinical trials have evaluated the efficacy of therapeutic agents used in naturally occurring cases of coliform mastitis, especially for the peracute form of the disease.

Most of the controversy has centered on the rational use of antimicrobial agents. The use of antimicrobial agents for the treatment of coliform mastitis has been questioned for several reasons:

- **Clinical signs** are primarily due to the effects of endotoxin in the mammary gland, with formation of endogenous inflammatory mediators within the udder and their subsequent release into the systemic circulation.
  - **The severity of clinical signs** are correlated with the number of bacteria in the affected gland.
  - **Most mild cases of coliform mastitis** (abnormal milk but normal gland and cow) are self-limiting and resolve without antimicrobial therapy. However, a small percentage of these mild clinical cases develop persistent infection.
  - **There is speculation that the use of antibiotic therapy for the treatment of coliform mastitis** is not effective. The benefit-cost ratio is.
  - **The antimicrobial susceptibilities of E. coli isolates from coliform mastitis vary considerably; drug susceptibility determination is not routinely recommended because the breakpoints have not been validated and the bacteria come from diverse sources in the environment.**

**Parenteral antimicrobial agents**

Broad-spectrum antimicrobial agents should be administered parenterally to cattle with systemic signs of disease (abnormal cow), preferably by the intravenous route initially, followed by intramuscular administration to maintain appropriate plasma concentrations. The first reason to administer parenteral antibiotics is that the severity of clinical signs is correlated with the numbers of bacteria in milk from the affected gland. The second main reason to administer parenteral antibiotics is to combat bacteremia, which is present in 32–48% of severely affected cattle.

Based on pharmacokinetic/pharmacodynamic values, the results of experimentally induced and naturally acquired infections, and in vitro antimicrobial susceptibility testing (if this has any relevance to in vivo susceptibility), most E. coli isolated from the mammary glands of cattle are theoretically susceptible to...
third-generation cephalosporins (such as ceftiofur), fourth-generation cephalosporins (such as cefquinome), fluoroquinolones, gentamicin, amikacin, trimethoprim–sulfadiazine and oxytetracycline.

- **Ceftiofur** is a third-generation cephalosporin that is resistant to beta-lactamases and has excellent in vitro activity against *E. coli*. When given parenterally to cows with experimental coliform mastitis, ceftiofur did not produce drug concentrations in milk above the reported minimum inhibitory concentrations for coliform bacteria. However, when administered to cows with naturally occurring coliform mastitis, ceftiofur-treated cows (22 mg/kg BW intramuscularly every 24 h) were three times less likely to die or be culled from the herd and had more saleable milk than nontreated cattle.

- **Cefquinome** is a fourth-generation cephalosporin that is resistant to beta-lactamases and has excellent in vitro activity against *E. coli*. Parenteral cefquinome therapy (1 mg/kg BW intramuscularly twice at 24 h apart), with or without intramammary cefquinome (75 mg, three times at 12 h intervals), increased the bacteriological cure rate and significantly improved clinical recovery and return to milk production in experimentally induced *E. coli* mastitis.

- **Enrofloxacin**, a fluoroquinolone with excellent in vitro activity against *E. coli*, given intravenously initially then subcutaneously (5 mg/kg BW) was effective in treating experimentally induced *E. coli* mastitis. In general, parenterally administered enrofloxacin increased the rate of *E. coli* clearance from the infected mammary gland.

- **Gentamicin** has been used on an extralabel basis for the treatment of acute and peracute coliform mastitis because more than 90% of isolates from milk from affected cows are sensitive in vitro. However, the parenteral administration of gentamicin at 2 g intramuscularly every 12 hours until the appetite improved to dairy cows with mastitis predicted to be associated with Gram-negative bacteria did not result in significant improvement compared to cows with similar mastitis that did not receive an antimicrobial or received erythromycin.

- **Trimethoprim–sulfadiazine** (trimethoprim 4 g, sulfadiazine 20 g, intramuscularly every 24 h for 3–5 d) is efficacious in treating naturally acquired cases of coliform mastitis. The recovery rate of cows with clinical mastitis due to coliform bacteria susceptible to sulfadiazine–trimethoprim was 89% compared to 74% in cows infected with coliform resistant to the combination given parenterally, combined with NSAIDs and complete milking of affected quarters several times daily. Sulfadiazine or sulfamethazine (sulfadimidine) are preferred to sulfadoxine because the latter produces much lower milk concentrations after parenteral administration.

- **Oxytetracycline** (16.5 mg/kg BW intravenously every 24 hours for 3–5 d), combined with intramammary cephapirin (200 mg) and supportive care (intravenous or oral fluids, flunixin meglumine, stripping of the mammary gland) was more effective in treating coliform mastitis than similar treatment without antibiotics in cattle with naturally acquired mastitis.

### Intramammary antimicrobial agents

Intramammary preparations of antimicrobial agents can be infused into the affected quarters after they have been stripped out completely at the start and end of the day. The initial choice of antimicrobial will depend on previous experience of treatment efficacy in the herd.

- **Ceftiofur**: based on clinical response and the results of antimicrobial susceptibility testing of coliform isolates from cows with naturally occurring mastitis (if relevant to in vivo performance), ceftiofur is an excellent choice for intramammary infusion in suspected cases of coliform mastitis.

- **Gentamicin**: the intramammary infusion of 500 mg of gentamicin did not affect the duration or severity of experimentally induced coliform mastitis. The numbers of *E. coli* in the milk after intramammary inoculation were not affected by the intramammary infusion of gentamicin, despite maintaining a mean minimal gentamicin concentration in milk of 181 µg/mL between dose intervals. The infusion did not affect the body temperature or the magnitude and duration of the inflammatory process in the glands as measured by the SCCs and peak albumin and immunoglobulin concentrations in the milk. It should be noted that gentamicin is not approved for use in the treatment of bovine mastitis and in some jurisdictions is not approved for any use.

A study of the efficacy of intramammary antibiotic therapy for the treatment of naturally occurring clinical mastitis associated with environmental pathogens found no difference in the short-term clinical or bacteriological cure rates between quarters infused with 62.5 g amoxicillin every 12 hours for three milkings or 200 mg of cephapirin every 12 hours for two milkings, and those treated with 100 units of oxytetracycline intramuscularly every 12 hours immediately before milking for two or three milkings alone. However, the cost per episode of mastitis associated with the use of cephapirin was higher than the other two treatments, partly because of the longer milk withdrawal time (96 h) associated with the drug. The percentage of relapses was higher for cows in the oxytetracycline treatment group, especially when the mastitis-associated pathogen was an environmental *Streptococcus* sp.

### Stripping of affected quarter

An artificial intramammary environment has shown that milking 12 times daily could lead to elimination of *E. coli*, suggesting that frequent stripping would be an effective treatment. Indeed, stripping (augmented by oxytocin) is a popular but largely unsubstantiated recommendation for treating severe cases of coliform mastitis.

Oxytocin at 10–20 units per adult cow given intramuscularly, followed by vigorous hand massage and hourly stripping of the affected quarter, may assist in removing inflammatory debris. Oxytocin doses higher than this are not needed, and intravenous administration is not needed because oxytocin is rapidly absorbed when injected intramuscularly. Oxytocin can be repeated and used as long as an effect is obtained.

Effective removal of coliform bacteria and endotoxin will minimize their local effects in the mammary gland and decrease the systemic signs of endotoxemia. The main problems with stripping are the labor involved, the small volumes produced, the potential for creating additional pain and discomfort for the cow (and the producer when the cow kicks) and potential contamination of the environment if the secretion is stripped on to the ground. The role of frequent stripping, if any, in the treatment of clinical mastitis remains to be determined.

### Fluid and electrolyte therapy

Fluid and electrolyte therapy are essential for the treatment of acute and peracute mastitis.
coliform mastitis in order to counteract the effects of the endotoxemia. Isotonic polyionic electrolyte solutions (such as Ringer’s solution) are given at 80 mL/kg BW for the first 24 hours by continuous intravenous infusion, and at a slower rate than that over the following days. For a mature dairy cow (400–600 kg) a total of 32–48 L is therefore needed in the first 24-hour period, with 20 L given during the first 4 hours and the remainder over the next 20 hours. A favorable response is usually clinically evident in 6–8 hours. If the animal has not improved after 5 days of intensive fluid therapy (the 5-day rule for clinical improvement), the prognosis for survival is poor.

The large amounts of isotonic fluids and electrolytes which have been advocated and used are expensive to administer by continuous intravenous infusion and require monitoring over many hours. A possible alternative is the use of small volumes of hypertonic saline, which can be transported easily and administered rapidly. 

**Hypertonic saline** can be safely administered to cattle with endotoxin-induced mastitis.55 Hypertonic saline (7.2% NaCl) is given intravenously at 4–5 mL/kg BW intravenously over 4–5 minutes followed by immediate access to drinking water.56 The changes following administration of hypertonic saline include transient expansion of the plasma volume, hypotension, and hyperchloremia.57 The intravenous administration of hypertonic saline to clinically normal cows with access to water increases circulatory volume rapidly, induces slight strong ion (metabolic) acidosis and increases glomerular filtration rate.58 Fluid therapy is covered in detail in Chapter 2.

### Anti-inflammatory agents

NSAIDs are frequently administered as adjunctive therapy in coliform mastitis, particularly in the peracute form of the disease.59 **Ketoprofen** is the only currently available NSAID with documented efficacy in naturally acquired cases of coliform mastitis.

Ketoprofen has been evaluated as adjunctive therapy for the treatment of acute clinical mastitis in dairy cows, most cases of which are associated with Gram-negative pathogens.60 All cases were treated with 20 g sulfadiazine and 4 g trimethoprim intramuscularly followed by one-half dose daily until recovery. Ketoprofen was given at 2 g intramuscularly daily for the duration of the antimicrobial therapy. Recovery rates for the nonblind contemporary controls and the blind placebo controls were 84% and 71%, respectively. In the nonblind controlled ketoprofen and placebo-controlled ketoprofen treatment groups, recovery rates were 95% and 92%, respectively. The odds ratio (OR) of recovery was significantly high in the placebo-controlled study (OR = 6.8), and high but not significant in the nonblind controlled study (OR = 2.6). It was concluded that ketoprofen significantly improved recovery rate in clinical mastitis. A similar clinical field trial evaluating the efficacy of phenylbutazone and dipyrone for the treatment of mastitis caused mostly by coliforms revealed a beneficial effect but no difference between the efficacies of the two drugs.61 Neither phenylbutazone nor dipyrone is permitted for use in lactating dairy cattle in the USA, but their use is permitted in some countries.

The anti-inflammatory effect of either flunixin meglumine or dexamethasone was evaluated compared to controls in experimentally induced coliform mastitis. Dexamethasone at 0.44 mg/kg intravenously and flunixin meglumine at 11 mg/kg intravenously were both given 2 hours after inoculation of the *E. coli*, which is essentially a pretreatment administration because clinical signs are not evident at this time. Flunixin meglumine was also administered once 8 hours after the initial dose. Dexamethasone reduced the rectal temperature and the mammary surface temperatures, and prevented further increase in rectal temperature above 39.2°C. The response to flunixin meglumine was less than expected, which suggested that a higher dose of 2.2 mg/kg may be necessary in lactating dairy cattle. The administration of flunixin meglumine at 22 mg/kg intramuscularly or flurbiprofen at 2 mg/kg intravenously were both given during the first 9 hours after infection and lessened the decrease in rumen motility. Carprofen, a long-acting NSAID, reduced the fever, tachycardia and udder swelling associated with *E. coli*-endotoxin-induced mastitis.62 The long-acting properties of carprofen may be considered a therapeutic advantage over flunixin meglumine, which requires frequent dosing.

### Combination therapy

Fluid and electrolyte therapy and flunixin meglumine, in combination and individually, have been evaluated in a 3-year study of a large number of cows with toxic mastitis.63 Cows were allotted to one of three groups:

- **Fluid therapy** (45 L of intravenous isotonic electrolyte solution) and flunixin meglumine at 2 g
- **Fluid therapy intravenously only**
- **Flunixin meglumine only**

All cases were treated with parenteral and intramammary antimicrobial agents, oxytocin and calcium borogluconate. There was no significant difference in the rate of survival between the treatment groups, and 54% of the cows survived.

### CONTROL

The control of coliform mastitis is characteristically difficult, unreliable and frustrating. Several cases of fatal peracute coliform mastitis may occur in a herd of 100 cows during a period of a year, in spite of the existence of apparently excellent management. The general principles of mastitis control that have been effective for the control of *S. aureus* and *S. agalactiae* mastitis have been unsuccessful for the control of coliform mastitis because infection of the mammary gland occurs by direct contact with the environment, usually between milking. For the control of coliform mastitis, the emphasis is on the prevention of new infection. Core lipopolysaccharide antigen vaccines are useful and are discussed below.

### Management of outbreaks

When an outbreak of peracute coliform mastitis is encountered the following procedures are recommended in an attempt to prevent new cases:

- Culture milk samples and obtain a definitive etiological diagnosis (in other words, put a name to the causative pathogen)
- Examine the bedding for evidence of heavy contamination with coliform bacteria. If sawdust or wood shavings are being used, replace with sand, if possible, or change more frequently
- Conduct a general clean-up of the stall and lounging areas
- Improve premilking hygiene
- Examine milking machine function
- Allow cows access to fresh feed immediately after milking to ensure that they remain standing for at least 30 minutes to allow time for the streak canal to close.

### Housing and environment

The normal presence of coliform bacteria in every aspect of the cow’s environment must be recognized but every effort must be made to avoid situations that allow a build-up of bacterial numbers. This is especially important in dairy herds that have been on a mastitis control program, resulting in a high percentage of cows with low SCCs in their milk, which increases their susceptibility to coliform mastitis. The overall level of sanitation and hygiene must be improved and maintained in these herds.

### Bedding

Most coliform infections in periparturient cows occur very early in the dry period or just before calving, and so efforts to
Prevent infection should be centered on these periods. Management of the dry cow environment may provide the best opportunity for prevention of infection. While no reliable recommendations are available, cows that are housed during part or all of the day or night should be bedded on clean and dry bedding and not overcrowded, to prevent heavy fecal contamination. When possible, dry and preparturient cows are best maintained on pasture. There is an urgent need for the determination of optimum space and bedding requirements for the lounging areas of dairy cows kept under loose housing. Bedding should be kept as dry as possible. Excessively wet bedding should be removed from the back one-third of the stalls daily and replaced with fresh bedding. The addition of lime may decrease bacterial growth. Sawdust and shavings harbor more coliform bacteria than straw, and require special attention. The buildup of high numbers of coliform bacteria in the bedding of cow cubicles can be controlled by the daily removal of the sawdust from the rear of the cubicle and rebeding with clean sawdust, which is usually of low coliform count. The use of a parafomaldehyde spray on sawdust bedding reduced the coliform count for 2–3 days but it returned to its presanitation level in 7 days. When outbreaks of coliform mastitis are encountered that are possibly associated with heavily contaminated sawdust or shavings, the bedding should be removed immediately and replaced with clean, fresh, dry straw. The use of sawdust or shavings as bedding should be avoided if possible. Sand is now considered to be the ‘gold standard’ and the most suitable alternative.

Regular daily cleaning of barns

This is necessary to minimize contamination of teats. In free-stall and loose-housing dairy barns, every management technique available must be used to insure that cows do not defecate in their stalls and increase the level of contamination. This requires daily raking of the bedding in free-stall barns and adjusting head rails to insure that cows do not lie too far forward in the stall and to insure that they defecate in the alleyway.

In dairy herds that are confined for all or part of the year, the level of contamination usually increases as herd size increases; commonly the ventilation is inadequate. This leads to excessively humid conditions, which promote the development of coliform bacteria in wet bedding. This will require increased attention to sanitation and hygiene.

Milking procedures

Postmilking teat dipping with a disinfectant has little effect on reducing the incidence of coliform mastitis because contamination of the teats occurs between milkings rather than at milking. Thus, one logical approach to the control of coliform mastitis is to reduce environmental contamination. In the event of gross fecal contamination of the udder and teats, additional time and care will be required at milking time. Premilking udder preparation can significantly influence milk quality. Lowest bacterial counts in milk are observed when the teats of cows are cleaned with water followed by thorough drying with paper towels, or when a teat disinfectant is applied to the teats followed by drying with paper towels. In addition, premilking teat disinfection in association with good udder preparation reduces the rate of intramammary infections by environmental pathogens by about 51% compared with good udder preparation only.62

Premilking teat disinfection

Many dairy producers have now incorporated premilking teat disinfection into their mastitis control strategy, and many different teat dips are being used.62 Premilking teat dips containing 0.25% iodine, 0.1% iodophor, 0.25% iodophor and 0.55% iodophor–1.9% linear-dodecyl benzene sulfonic acid have been evaluated and have provided consistent results. Premilking and postmilking teat disinfection, in association with good udder preparation, are significantly more effective in prevention of environmental pathogen intramammary infection than good udder preparation and postmilking teat disinfection. No chapping or irritation of teats was observed. However, premilking teat disinfection did not reduce the incidence of clinical mastitis.

Postmilking external teat sealant

A latex barrier teat dip that formed a physical seal between the teat and the environment reduced the incidence of new coliform intramammary infections during lactation. The efficacy of this barrier product was thought to be due to the persistency of the dip on teats between milkings; however, it was not consistently successful. A barrier teat dip containing 0.55% chlorhexidine was effective in reducing intramammary infection associated with both environmental and contagious pathogens. The incidence of E. coli intramammary infections was reduced but the incidence of Serratia spp. and Pseudomonas spp. was increased, while the incidence of environmental streptococcal intramammary infection was unchanged by using the experimental barrier dip compared with the results using a 1% iodophor dip.

Nutrition

Vitamin E or selenium deficiency decreases neutrophil chemotaxis into the mammary gland and decreases the intracellular killing of bacteria by neutrophils. It is therefore important to ensure that vitamin E and selenium intakes are adequate; this is best achieved by daily ingestion of 1000 IU vitamin E and 3 mg selenium for dry cows and daily ingestion of 400–600 IU vitamin E and 6 mg selenium for lactating cows.

Prevention of infection during dry period

Considerable movement of coliform bacteria can occur from the teat apex into the teat sinus in cows that are not being milked, and so cows that are due to calve should be kept on grass or moved into a clean area at least 2 weeks before calving, their udders and teats washed daily if necessary, and teat dipping with a teat disinfectant begun 10 days before calving. This is particularly necessary for older cows and those that are known to be easy milkers. The teats of those cows that are ‘leakers’ just before calving may have to be sealed with adhesive tape or collodion to minimize the chance of infection.

Recumbent cows

Cows that are recumbent and unable to stand (e.g. the downer cow) should be well bedded on clean dry straw; their udders should be kept clean and dry, and the teats should be dipped with a teat disinfectant. Strict hygiene must be practiced when using teat siphons and teat creams, and strict asepsis observed when doing teat surgery.

Milking machine

Irregular vacuum fluctuations in the milking machine may induce coliform mastitis in quarters exposed to a high level of contamination. The operation and sanitation of the milking machine, especially those parts in direct contact with the teats, must therefore be examined.

Vaccination

Core lipopolysaccharide antigen vaccine

The vaccination of cows during the dry period and early lactation with core lipopolysaccharide antigen vaccine (such as the Re mutant Salmonella typhimurium or the Re mutant E. coli O111:B4 (J5 vaccine)) provides one tool to reduce the incidence and severity of clinical coliform mastitis.63 These vaccines are available in the USA and are based on mutated Gram-negative bacteria with exposed core antigens of lipopolysaccharide. The core antigen (lipid A component) is uniform between bacterial species possessing lipopolysaccharide and is immunogenic. On theoretical grounds, the Re mutant (S. typhimurium) should provide better
protection than the Rc mutant (E. coli J5) because the lipid A component is more accessible to the immune system; however, comparative studies of vaccine efficacy have not been performed. 

The Rc and Rc mutant vaccines are protective against natural challenge to Gram-negative bacteria, and in most, but not all studies, reduce the incidence and severity of clinical Gram-negative bacterial mastitis in lactating dairy cows. In a prospective cohort study in two commercial dairy herds, during the first 90 days of lactation, cows vaccinated with E. coli J5 vaccine were at five times lower risk of developing clinical coliform mastitis than unvaccinated cows. This is corroborated with the observation that cows with naturally occurring serum IgG ELISA titers higher than 1:240 against the Gram-negative core antigen of E. coli J5 had 5.3 times lower risk of developing clinical coliform mastitis than cows with lower titers. Vaccination reduced the severity of clinical signs following intramammary experimental challenge with a heterologous E. coli strain. In cows vaccinated with the J5 bacterin at drying off, 30 days after drying off and within 48 hours after calving, and challenged 30 days after calving with a strain of E. coli known to cause mild clinical mastitis, the third milkings after vaccination,67 these cows had lower milk production than in vaccinated cows. Two studies indicate that core lipopolysaccharide antigen vaccine (the Rc mutant) indicated that herd vaccination programs were predicted to be profitable when more vaccines have the potential to have protective effects of their decrease in cardiovascular reserve. The vaccines should not be administered at the same time as other Gram-negative vaccines.

**ENVIRONMENTAL STREPTOCOCCI**

**Etiology** Streptococcus uberis, Streptococcus dysgalactiae spp. dysgalactiae, other Streptococcus spp., and occasionally Enterococcus spp.occasionally

**Epidemiology** Common cause of subclinical and clinical mastitis in herds and countries that have controlled contagious mastitis. Responsible for approximately one-third of all cases of clinical mastitis in herds without contagious pathogens. Rate of infection high during first 2 weeks following drying off and 2 weeks before calving. Duration of infection usually short (<8 d). Prevalence of infection at calving: 11% of cows and 3% of quarters. Bedding materials (high in straw bedding) most important source of environmental streptococci, bacteria can be isolated from many different feedstuffs and several locations on cow (teats, rump, feces, saliva, lips, nips). Bacterial numbers low in sand, which is bedding of choice.

**Clinical findings** Abnormal milk, abnormal gland, usually no systemic signs. Recovery in two to three milkings.

**Clinical pathology** Culture of milk

**Necropsy findings** Not applicable

**Diagnostic confirmation** Culture bacteria from milk and milk SCC

**Differential diagnosis** Cannot differentiate from other causes of subacute and acute mastitis without culture of milk

**Treatment** Antimicrobial intramammary infusions increase bacteriological cure rate and decrease percentage of relapses. Intramammary antibiotics should be administered to all clinical cases of mastitis due to environmental streptococci

**Control** Decrease exposure of teat end to pathogens by attention to environment, dry bedding, sand for bedding, premilking hygiene and premilking germicide teat dipping. Dry cow therapy with penicillin G, cloxacillin, erythromycin and first-generation (cephalin) or second-generation (ceftiofur) cephalosporins. Application of an internal teat sealant of bismuth subnitrate at dry-off may decrease new infection rate in dry period.
ETIOLOGY
Streptococcus uberis and Streptococcus dysgalactiae spp. dysgalactiae and the enterococci are the most commonly isolated environmental streptococci from intramammary infections. Other uncommon environmental streptococci involved in bovine mastitis include Streptococcus equi var. zoeoepidemicus,1 Streptococcus viridans, S. equinus (S. bovis), Streptococcus pyogenes and Streptococcus pneumoniae.
Both S. uberis and S. dysgalactiae are widespread in the animal’s environment and on the skin of the teats. Two genotypes of S. uberis (S. uberis = type 1, Streptococcus paraberis = type II), with marked differences in their capacity to invade quarters and to cause mastitis, have been identified.2,3 Enterococcus spp. are also a common cause of environmental intramammary infections.4 The streptococcal species most commonly isolated from intramammary infections all hydrolyze esculin (S. uberis, Streptococcus spp., Enterococcus spp.).

EPIDEMIOLOGY
Occurrence and prevalence of infection
In countries where the prevalence of intramammary infections due to the contagious pathogens S. agalactiae and S. aureus has been reduced or eradicated, the proportion of intramammary infections associated with environmental streptococci has increased markedly, these organisms are a leading cause of both subclinical and clinical mastitis in dairy cattle worldwide.4,5 S. uberis is now a common cause of intramammary infection occurring during the dry period, with most clinical cases occurring during the first part of lactation. Many infections acquired during the dry period persist to lactation and contribute to the incidence of clinical mastitis in early lactation. The rate of new infection due to environmental streptococci is elevated during the first 2 weeks following drying off and the 2 weeks prior to calving; the rate of new infections is greater during the first month of lactation than during the remainder of the lactation. Approximately 50% of new infections occur during the dry period and 50% in the early part of lactation. The rate of new infections during the dry period is about five times greater than during lactation.4 Based on data from surveys of milk samples over a 10-year period, the point prevalence of infection of environmental streptococci was 4% of quarters and 12% of cows.6 The percentage in heifers at calving is similar to that in cows. The prevalence of environmental streptococci isolation at drying off and calving was 2.5% and 3.0%.6 Environmental streptococcal intramammary infections are usually short-lived (< 28 days), with only a small percentage becoming chronic.4,7

The most important change in the epidemiology of bovine mastitis over the past decade has been the rise in the importance of environmental pathogens, mainly causing clinical mastitis, relative to contagious pathogens. Remarkable increases in both the coliforms and environmental streptococci as causes of clinical mastitis have occurred.8 The percentage of clinical cases of mastitis from which environmental streptococci can be isolated ranges from 14% in Ontario to 26% in the UK. When expressed as a percentage of clinical cases from which a major pathogen was isolated, environmental streptococci are isolated in 37–45% of cases.

Source of infection
The environmental streptococci, especially S. uberis, have been isolated from bedding materials and the lips and tonsils of cows, with the abdominal skin of cows often harboring the largest population.9 Some cows are permanently colonized with S. uberis and may pass large numbers of the bacteria in the feces. Fecal shedding is believed to play an important role in the maintenance of S. uberis populations on dairy farms, and is the likely source of large numbers of the organism in straw bedding on farms where this form of Intramammary infection is common.10 The numbers of environmental streptococci in organic bedding materials vary with the type of bedding. Large numbers of S. uberis are found in straw bedding and much lower numbers in sawdust and wood shavings. The numbers of streptococci recovered from the teats of cows bedded on sawdust are lower than those bedded on straw. Long straw used in calving box stalls or as bedding in loose housing can be a source of considerable exposure to environmental streptococci.

S. dysgalactiae can also be found in the environment of dairy cattle and has been isolated from the tonsils, mouth and vagina, and the mammary glands. It has characteristics of both a contagious and an environmental pathogen and some categorization schemes place it in the contagious category, although it is primarily an environmental pathogen. S. dysgalactiae is also associated with summer mastitis, which affects dry cows and heifers during the summer months. It has been isolated from the common cattle fly Hydrotoma irritans, which may be involved in the establishment and maintenance of bacterial contamination of teats. S. dysgalactiae may colonize the teat prior to infection with A. pyogenes and anaerobic bacteria such as P. indolicus and F. necrophorum.

Risk factors
Environmental risk factors
The major risk factor for environmental streptococcal infection is exposure of the teat end to mastitis pathogens in the environment. Transmission is predominantly from the environment.7 Exposure of uninfected teats to environmental streptococci can occur during the milking process, between milkings, during the dry period and prior to parturition in first-lactation heifers. The rate of new infections is greatest during the summer months in North America.4

Housing and management practices on dairy farms may contribute to contamination of bedding materials and exposure to environmental streptococci. Housing facilities that predispose to the accumulation of feces on cows will increase the rate of exposure of the teat end to pathogens. Straw bedding appears to increase the risk of S. uberis mastitis,11 and an increase in S. uberis mastitis cases occurs when cows are housed in deep straw pack.

Pastured cattle are generally at reduced risk for environmental streptococcal mastitis when compared to cows in confinement housing. However, certain pasture conditions, such as areas under shade trees, poorly drained ground surfaces, ponds and muddy areas, may result in a high rate of exposure to the pathogens. The environmental streptococci are the most significant environmental pathogen in New Zealand dairy herds where cows spend almost 100% of their time on pasture.12

S. dysgalactiae is commonly isolated from heifers and cows in the dry period and is one of the most prevalent pathogens isolated from cases of summer mastitis. The spread of S. dysgalactiae between cows within dairy herds may occur directly or by way of the milking machine or environment.

Animal risk factors
The risk of new infections is influenced by the stage of lactation and parity of the cow. The rate of new infection is highest during the 2 weeks following drying off and the 2 weeks prior to calving. The high rates of new infection following drying off may be associated with the lack of flushing action of milking, changes in the composition of the mammary secretion, which may enhance the growth of the pathogens, and the lack of a keratin plug in the streak canal. The primary defense mechanisms for S. uberis are the length of the teat canal and the amount of keratin in the lining.13 Antimicrobial dry cow therapy reduces the infection rate in the early part of the dry period but has no or little effect on
preventing infection with *S. uberis* at the end of the dry period. The increase in susceptibility to infection just prior to parturition may be associated with the lack of milking when the gland is accumulating fluid, loss of keratin plugs from streak canals, or immunosuppression of the periparturient period. The rate of infection is also higher in older cows than for either heifers or cows in second lactation, and highest during the summer months for both cows in lactation and cows in the dry period. This is in contrast to contagious pathogens, where exposure occurs primarily during the milking process.

Pathogen risk factors

*S. uberis* is ubiquitous in the cow’s environment with multiple environmental habitats. Consequently the mammary gland is exposed continuously to the pathogen during lactation and the dry period and infections are associated with a large variety of strains. Several virulence factors of *S. uberis* and *S. agalactiae* have been identified that are important in the pathogenesis of environmental mastitis. Antiphagocytic factors allow *S. uberis* to infect and multiply in the gland, and to adhere to and invade the mammary tissue. Bovine mammary macrophages are capable of phagocytosis of the organism but certain strains of *S. uberis* are capable of resisting phagocytosis by neutrophils, because of their hyaluronic acid capsule. The ability of *S. uberis* to invade the bovine mammary epithelial cells could result in chronic infection and protection from host defense mechanisms and the action of most antimicrobial agents, which may explain the intractable response to therapy in some cases. However, most ‘intractable’ infections are due to an inappropriately short duration of treatment.

*S. agalactiae* behaves like both a contagious and an environmental pathogen and can invade bovine mammary epithelial cells, which may explain the persistence of infection. Different biotypes of *S. agalactiae* have been identified, and strains can possess several antiphagocytic factors, including M-like protein, alpha-2-macroglobulin, capsule and fibronectin binding, and virulence factors, including hyaluronidase and fibronolysin.

An existing intramammary infection due to *C. bovis* is a risk factor for environmental streptococcal infection through an unidentified mechanism.

**Economic importance**

The major economic losses associated with environmental streptococcal mastitis are caused by clinical mastitis resulting in the loss of production, milk withholding, premature culling, increased labor, and costs of therapy and veterinary services. 88% of the loss associated with clinical mastitis is attributed to loss of milk production and milk withholding. Pluriparous cows lost 2.6 times as much as first-call heifers, and cows less than 100 days in milk lost 1.4 times more than cows more than 150 days in milk.

**PATHOGENESIS**

Infections with *S. dysgalactiae* artificially induced in goats are indistinguishable from mastitis associated with *S. agalactiae* and the pathogenesis is probably similar in all streptococcal mastitides. In experimental infection of dairy cows with *S. uberis* there is acute inflammation, resulting in the accumulation of large numbers of neutrophils in the secreatory acini in 24 hours. After 6 days, the neutrophil response is still evident but there is cellular infiltration, septal edema, extensive vacuolation of secretory cells, focal necrosis of alveoli, small outgrowths of the secreatory and ductular epithelium, and widespread hypertrophy of the ductular epithelium. The organism is present free or phagocytosed, in macrophages in the alveolar lumina, adherent to damaged secretory or ductular epithelium, in the subepithelium and septal tissue, and in lymphatic vessels and lymph nodes. The macrophage is important as the primary phagocytic cell but the marked neutrophil response may be ineffective as a defense mechanism. It is hypothesized that the marked neutrophil response following infection with *S. uberis*, rather than the organism, may be responsible for the most of the effects of the mastitis. The current consensus is that environmental streptococci (with the possible exception of *S. dysgalactiae*) are not contagious pathogens.

**Differential diagnosis**

Streptococcus uberis mastitis in dry cows may be sufficiently severe to resemble mastitis associated with *A. pyogenes*. Diagnosis depends on cultural examination of the milk.

**TREATMENT**

**Antimicrobial agents**

The in vitro susceptibility of environmental streptococci to antimicrobial agents is high. Most isolates of *S. uberis* and *S. dysgalactiae* are susceptible to penicillin, novobiocin, amoxicillin and cephalixin. A high percentage (96%) are also susceptible to tetracycline, but susceptibility to aminoglycosides is much lower. Most cases of clinical mastitis associated with *S. uberis* and *S. dysgalactiae* respond well to intramammary infusions of penicillin, cephalosporins, cloxacillin, erythromycin and tetracyclines. Spontaneous cures can also occur. Clinical cases in lactating cows should be treated by at least two intramammary infusions 12 hours apart; this may produce clinical cure but fail to produce a bacteriological cure. Subclinical infections in late lactation may be left until the dry period. For clinical cases in the first 100 days of lactation there is substantial economic benefit from treatment. Some cases associated with strains of *S. uberis* appear intractable to treatment; extended treatment is necessary in these animals. Failure of treatment may be due to epithelial cell invasion and movement of the bacteria into subepithelial layers, possibly reducing the effectiveness of the antimicrobial. Extended therapy (for 5 or 8 days) with intramammary cepfiorf (125 mg), pirlimycin (50 mg) or penethemate hydroxide, dihydrostreptomycin sulfate and framycetin sulfate, every 24 hours, increases the bacteriological cure rate for cattle with experimentally induced *S. uberis* mastitis.

In a study of 1148 cases of subclinical environmental streptococcal mastitis in New York, commercially available intramammary infusions were more effective than untreated controls (66% bacteriological cure), with
the following bacteriological cure rates: amoxicillin (90%), penicillin (82%) and cloxacillin (79%).

Treatment using oxytocin and frequent stripping of the affected glands without intramammary antibiotic administration is not recommended because cure rates are much lower. Moreover, not administering antimicrobial agents results in a higher relapse rate. Many of the relapses were associated with the environmental streptococci and therefore intramammary antimicrobial treatment should be routinely performed. In particular, because clinical mastitis with an abnormal gland or abnormal cow induces some pain and discomfort in the cow, withholding an effective treatment (antimicrobial agents) cannot be condoned on animal welfare grounds.

Reinfec tion may occur quickly if the contributory causes are not corrected. Infections with S. zooepidemicus do not respond well to treatment with penicillin. Mastitis associated with S. pneumoniae responds well to local treatment with penicillin in large doses (300,000 units per infusion) but quarters allowed to go without treatment for any length of time suffer complete loss of function. All cases of mastitis associated with this bacteria should receive parenteral treatment with penicillin.

CONTROL

The control of mastitis due to environmental streptococci is achieved by decreasing the exposure of pathogens to the teat end and by increasing the resistance to intramammary infections. A specific control recommendation for environmental streptococci mastitis is not to bed on straw, but this may not be a practical or economic recommendation for some producers. If straw bedding is used, a reduction in the teat end exposure to S. uberis can result from frequent (daily) replacement of bedding.

Reducing the exposure of the teat end to pathogens depends on maintenance of a clean and dry environment. Special attention must be directed to the dry cow and close-up heifer housing, the calving area, lactating cow housing, and the milking parlor and milking hygiene. Organic bedding materials such as straw that support large numbers of environmental pathogens should be kept dry. Sand is the ideal bedding material because it has the lowest number of coliform and environmental pathogens. Wet and damp areas in the back part of free stalls and tie stalls promote exposure to environmental pathogens. Milking time hygiene should emphasize milking of clean, dry teats and udder, with a properly functioning milking machine.

Predipping with a teat dip germicide may reduce environmental mastitis by as much as 50% but this reduction does not occur in all herds.

Dry cow therapy to prevent new infections has not been as successful for the control of all causes of environmental mastitis as it has been for contagious mastitis. However, dry cow therapy is more effective against the environmental streptococci than against coliform bacteria. Application of an internal teat sealant of bismuth subnitrate at dry-off is effective in preventing infections associated with S. uberis during the dry period.

A long-acting intramammary infusion dry cow therapy containing 250 mg cephalixin administered after the last milking of lactation reduced the incidence of new infections due to S. uberis from 12.3% to 1.2%. Clinical infections during the dry period were most prevalent in quarters identified as having open teat canals. Fewer open teat canals were observed among treated quarters over the first 4 weeks of the dry period. It is proposed that the teat canal of treated quarters closed earlier than those of untreated quarters. Most of the new infections in the untreated controls occurred within the first 21 days of the dry period. Normally, the teat canal is dilated for up to 7 days after drying off, with a keratin plug then forming over the following 14–21 days. It is suggested that once a physical keratin seal has formed in the teat canal after drying off, an uninfected quarter has a very low risk of infection over the remainder of the dry period. Treated quarters had a lower incidence of new clinical infections during the next lactation and lower SCCs.

Vaccination

Experimentally, multiple intramammary vaccinations with whole killed S. uberis cells resulted in complete protection against experimental infection in cattle. Bacteria could not be isolated from the quarters after challenge, and protection occurred in the absence of a marked neutrophil response. Preparations containing plasminogen activator may form the basis of a vaccine against S. uberis. Vaccines are presently commercially unavailable, and vaccination is not currently recommended as part of the control program for mastitis due to environmental streptococci.

ARCANOBACTERIUM PYOGENES

ETIOLOGY

Arcanobacterium pyogenes (formerly Actinomyces pyogenes and Corynebacterium pyogenes) causes two forms of severe clinical mastitis: sporadic cases of suppurative mastitis, mostly in housed cattle, referred to as pyogenes mastitis, and a clinically similar disease that occurs in outbreaks in cattle during the summer months in Europe and Scandinavia and is referred to as summer mastitis. Successful transmission of infection has been performed, but the bacteria is rarely present in pure culture in the naturally occurring disease and is not the specific cause of summer mastitis. When the organism is applied to the teat skin at the end of the teat, infection of the quarter does not occur unless the teat end is injured, when anaerobic bacteria are also involved in the infection.
Etiology Arcanobacterium pyogenes, formerly known as Actinomyces pyogenes of Corynebacterium pyogenes

Epidemiology Important cause of sporadic suppurative mastitis, most common in dry cows or pregnant heifers. Outbreaks occur in Europe in summer (called summer mastitis) associated with seasonally active biting flies, such as Hydrotoea irritans. Other bacteria (Streptococcus dysgalactiae and Peptostreptococcus indolicus) may be required to initiate clinical mastitis.

Clinical findings Gland is severely swollen and hard, usually only one quarter affected. Secretion from infected quarters initially watery with clots, later purulent. Initially severe systemic signs including fever, inappetence, tachycardia, depression, mortality rate up to 50%. In cattle surviving the initial infection, the affected quarter becomes abscessed, with drainage of purulent material at the base of the teat.

Clinical pathology Culture of milk

Necropsy findings Abscesses in one gland and severe systemic reaction are strong presumptive necropsy findings of A. pyogenes mastitis.

Differential diagnosis Cannot definitively differentiate from other causes of acute mastitis without culture of milk; however, presence of abscesses in mastitis is strongly suggestive of A. pyogenes.

Treatment Responds poorly to treatment with parenteral procaine penicillin G or oxytetacycline and intramammary penicillin. Affected quarter is almost always lost for milk production.

Control Intramammary infusion with dry cow preparation every 3 weeks during the dry period. Control fly populations. Isolate cows with draining abscesses.

In summer mastitis the purulent material in the quarter usually contains A. pyogenes as a primary pathogen but the severity of the disease is determined by the presence of anaerobes such as P. indolicus, S. dysgalactiae, F. necrophorum, P. melaninogenica, Fusobacterium spp., a microaerophilic, Gram-positive coccus (Stuart–Schwan coccus) and other Bacteroidaceae and Micrococcus spp. are also found. These bacterial species are found on the teats and conjunctiva and in the oral cavity of healthy cattle. P. necrophorum was recovered almost exclusively from the oral cavity, P. indolicus and A. pyogenes most frequently from teat skin, and isolates of P. melaninogenica subsp. levis were evenly distributed between conjunctiva and teat tip samples. There is also a distinct seasonal pattern of the isolation of the pathogens, which corresponds closely to the seasonal activity of the fly Hydrotoea irritans. It has also been proposed that S. dysgalactiae is the primary cause, and the others secondary invaders, but all these bacteria are capable of causing suppurative mastitis when infused into the udder. A. pyogenes alone establishes itself readily in mammary tissue after experimental introduction but causes only a subclinical disease, but inclusion of summer mastitis exudate provokes the classical syndrome of summer mastitis.

Experimental infections with A. pyogenes and P. indolicus cause a much more serious disease, and one less responsive to treatment if the infection is introduced into a dry quarter instead of into a lactating one. The bacterial flora in cases of summer mastitis is quite variable. In some years in the UK, many cases are apparently due to pure infections of M. haemolytica. In pyogenes mastitis, A. pyogenes is often found in pure culture but the other bacteria listed in summer mastitis are also common accompaniments. Actinomyces ulcerans is an uncommon cause of a subacute mastitis.

EPIDEMIOLOGY Occurrence and prevalence of infection

Bovine mastitis associated with A. pyogenes occurs sporadically and is most common in dry cows or pregnant heifers, although lactating cows may also be affected. A high prevalence is also recorded in heifer calves as young as 2 months. In the UK, Japan, northern Europe, Florida, and infrequently in a group of countries scattered all over the world, there is a much higher incidence of suppurative ‘summer mastitis’ during the summer months when nonlactating females are left at pasture and not kept under close observation. In the UK 20–60% of farms are affected, the same herds are affected every year and about 40% of farms never experience the disease.

Source of infection and mode of transmission

The portal of infection is unknown, although it is presumed to be via the teat canal. The method of spread is usually peracute with a severe systemic reaction and loss of function of the entire quarter. The disease has been reproduced by inoculation of the mammary gland of pregnant heifers with A. pyogenes, F. necrophorum, and P. indolicus. All animals developed moderate to severe clinical mastitis: four out of 10 animals recovered completely and had a normal lactation after calving. In six of 10 animals, the course of the disease was severe and affected quarters failed to produce milk after calving.

CLINICAL FINDINGS

Mastitis associated with A. pyogenes is usually peracute with a severe systemic reaction, including fever (40–41°C, 104–105°F), rapid heart rate, complete inappetence, and severe depression and weakness. Abortion may occur during this stage. In almost all cases only one quarter is affected, most commonly a front one. The teat is swollen and inflamed and the quarter is very hard, swollen and sore; the secretion is watery with clots early and later purulent, with a typical putrid odor. Affected cows usually carry a large fly population. If the cow survives the severe toxemia, the quarter becomes extremely indurated and abscesses develop, later rupturing through the floor of the udder, commonly at the base of the teat. These may be presented as being chronic cases but they are usually residual after an acute episode. True gangrene, such as occurs in staphylococcal mastitis, rarely if ever occurs in uncomplicated infections with
A. pyogenes but quarters may be so severely affected that sloughing occurs. Lameness in the hindlimb on the affected side occurs in some cases, and the limb joints may be swollen. The function of the quarter is permanently lost and cows that have calved recently may go completely dry. Severe thelitis with extreme thickening and obstruction of the teat is a common sequel. Partial or complete obstruction of the teat and damage to the teat cistern can also occur independently of an acute attack of mastitis. Fetal growth retardation is thought to be a feature of calves born to cows affected by summer mastitis during pregnancy.

Clinical Pathology
Isolation of the bacteria is required. Freezing of milk samples reduces the almost always rendered functionless. A. pyogenes by permanently drying the quarter off.

Necropsy Findings
Details of the pathology of the disease are not available.

Differential Diagnosis
The seasonal incidence of the disease in some areas, the acute inflammation of the quarter, the supplicative nature of the mastitis, the development of abscesses and the severe systemic reaction make this form of mastitis one of the easiest to diagnose clinically in cattle.

Treatment
Summer mastitis normally responds poorly to treatment and the affected quarter is typically lost for milk production. Failure of therapy is due to the extensive purulent processes in the udder and not to antimicrobial resistance. Bacterial isolates from cases of summer mastitis are susceptible to penicillin G and other beta-lactam antimicrobials. However, penicillin G has limited distribution throughout the inflamed udder. Penicillin G given parenterally to experimental cases of summer mastitis was effective in about 40% of cases if treatment was initiated within 32 hours after the onset of symptoms. In peracute cases parenteral treatment with sodium sulfadimidine or one of the tetracyclines is preferable and should be accompanied by repeated stripping of the quarter. Broad-spectrum antimicrobial agents are usually given by intramammary infusion but the quarter is almost always rendered functionless.

Affected quarters can also be treated by permanently drying the quarter off. The best method for permanently drying off a quarter is infusion of 120 mL of 5% povidone–iodine solution (0.5% iodine) after complete milk-out and administration of flunixin meglumine (1 mg/kg BW, intravenously). This causes permanent cessation of lactation in the quarter but does not alter total milk production by the cow.

Clearing of proteinaceous debris from the affected quarter may be aided by the intramammary application of proteolytic enzymes but the outcome as far as the quarter is concerned is unlikely to be much altered and amputation of the teat to facilitate drainage is a common treatment. Even with intensive therapy, at least 80% of quarters are rendered useless and many of those that respond are greatly reduced in productivity.

Control
The question of control of this form of mastitis centers largely on 'summer mastitis'. Many prophylactic measures, including infusing of the quarter when the cow is dried off, sealing the teat ends with collodion and vaccination with toxoid, have been tried but with inconclusive results. The most favored technique is the intramammary infusion with a dry cow preparation (e.g. cloxacillin 500 mg and ampicillin 250 mg in a long-acting base) at 3-week intervals during the dry period. Fewer frequent administration offers less protection. An alternative intramammary infusion procedure is to use cephalonium at 4-weekly intervals.

Repeated spraying of the udder, for example automatically at watering points, with a contact insecticide is commonly carried out during the fly season and is believed to be effective. An alternative to spraying is the use of insecticide-impregnated ear tags or pour-ons, but ear tags are decreasing in popularity. Careful daily examination of dry cows during the summer may enable affected quarters to be identified, the cows to be isolated and the quarters treated at an early stage and thus limit the spread of infection. In particular, cows with purulent material draining from an affected quarter need to be isolated from other cattle. Early treatment of teat lesions to limit bacterial colonization by bacteria, possibly transported by flies, is recommended. The known susceptibility of particular farms, and particular paddocks on those farms, demands proper care in planning the pasturing of dry cows during the danger period.

Review Literature

Mastitis of cattle associated with less common pathogens

Pseudomonas aeruginosa
Mastitis in cattle and sheep associated with Pseudomonas aeruginosa is rare and occurs usually as sporadic cases after intramammary infusion with contaminated material.

Etiology
P. aeruginosa is the most common cause, although other Pseudomonas spp. can cause disease.

Epidemiology
P. aeruginosa is common in the environment of cattle. Occasionally a number of animals in the herd are affected, the infection usually originating in contaminated water used for washing udders. The organism has the capacity to colonize inert materials such as loops of hose and the interior surface of water heaters, so that high bacterial concentrations may be in the water left in the hose between milkings. It may be an advantage in these circumstances to flush out the udder washing system before commencing each milking. Once the teats are contaminated, the entry of the organisms to the teats is facilitated by overmilking and by putting the milking cups on while the udder is still wet. Serious outbreaks in cows have also occurred in association with the use of a suspected contaminated mastitis infusion used as a dry period treatment. The cows became affected soon after calving.

Rarely, strains of this organism are highly virulent and cause fatal mastitis with generalized lesions. Less commonly still there is a high level of infection in a herd due to a contaminated water supply but with no clinical cases. Reinfection is common unless the source of infection is removed, even though there is apparent cure by treatment with spectinomycin.
CLINICAL FINDINGS
The mastitis may be clinically severe and the mortality rate as high as 17% of affected cows, or it may be subacute or chronic. Clinically there is a severe systemic reaction, acute swelling of the gland and the appearance of clotted, discolored milk; the function of the gland is usually completely lost at the first attack, but recurrent crises may occur.

CLINICAL PATHOLOGY
Culture of the organism in the milk is necessary to confirm the diagnosis.

NECROPSY FINDINGS
The disease can be fatal and the gross and histological findings are similar to other causes of clinical mastitis in cows.

DIFFERENTIAL DIAGNOSIS
Bovine mastitis associated with *Pseudomonas aeruginosa* must be differentiated from the many other forms of acute mastitis associated with this species; this can be done only by bacteriological examination of the milk.

TREATMENT
Treatment with antimicrobial agents is generally unsuccessful. Third-generation cephalosporins such as ceftiofur, aminoglycosides such as gentamicin, and fluoroquinolones are most likely to be efficacious in treating affected animals. Daily intramammary infusions of streptomycin (1 g) or neomycin (0.5 g), or both combined with polymyxin B, for 4 days, have been used.

CONTROL
The standard control program described later in the chapter should control the disease in cows. The oral administration of an organic iodine compound and vaccination with a killed autogenous vaccine are credited with bringing the disease under control in one herd.

PASTEURELLA SPECIES
Mastitis associated with *Mannheimia* (formerly *Pasteurella*) *haemolytica* and *Pasteurella multocida* is common in ewes, occurring in a peracute gangrenous form, but is comparatively rare in cattle and goats.

ETOLOGY
In cattle *M. haemolytica* and *P. multocida* are the causative organisms; *M. haemolytica* has also been isolated from many cases of summer mastitis in the UK.

EPIDEMIOLOGY
In cattle the disease is encountered rarely, and usually sporadically, but it may be a problem in individual herds, particularly where calves are reared by nurse cows.

CLINICAL FINDINGS
In cattle the mastitis is severe with fever, profound toxemic shock, weak pulse, tachycardia, and recumbency. The affected quarter is very swollen and the milk is watery, red-tinged and contains flakes. Disseminated intravascular coagulopathy may cause internal bleeding at many sites. All four quarters may be affected. There is complete cessation of milk flow in affected and unaffected quarters and subsequent fibrosis and atrophy. Newborn calves allowed to suck colostrum from affected cows may die of pasteurellosis.

Clinical pathology
Culture of the organism in the milk is necessary to confirm the diagnosis.

NECROPSY FINDINGS
The disease is not fatal in cows.

DIFFERENTIAL DIAGNOSIS
Bovine mastitis associated with *P. multocida* must be differentiated from the many other forms of acute mastitis associated with this species; this can only be done by bacteriological examination of the milk.

TREATMENT
In cattle, streptomycin administered by intramammary infusion is effective but tetracycline is preferred. Recurrence in quarters that appear to have recovered is not infrequent, and response to treatment is often poor.

CONTROL
The standard control program described later in the chapter should control the disease in cows.

3. Nocardia *brasilensis* and *N. farcinica* have also been recorded.

EPIDEMIOLOGY
Occurrence
With rare exceptions, nocardial mastitis in cattle has been recorded as a sporadic infection affecting only one or two cows in a herd. Accidental introduction of the causative bacteria into udders when infusions are being administered may create a herd problem. Nocardia is recorded as being a relatively common chronic mastitis in Cuba. Commencing in 1987, a large number of cases occurred in Canada. Confinement of dairy cattle in muddy pens has been associated with an increased incidence of nocardial mastitis.

Source of infection and mode of transmission
The bacteria is a common soil contaminant and probably gains entrance to the udder when udder washing is ineffective or udder infusion is not carried out aseptically. Nocardia can survive in ineffective teat dips and may be spread by their use. The disease is most common in freshly calved adult cows, particularly if infusion of the udder with contaminated materials is carried out in the dry period. *N. asteroides* is capable of surviving in mixtures used for intramammary infusion for up to 7 weeks. There is one record of a massive outbreak with many deaths that was probably due to the use of a contaminated homemade udder infusion.

Risk factors
A sharp increase in isolations of *N. asteroides* in milk samples at veterinary diagnostic laboratories in Canada was related to the extensive use of a particular dry period treatment. Teat dips containing recommended concentrations of iodine or dodecylbenzene are effective against *N. asteroides* whereas those containing chlorhexidine acetate are not effective. When the dip is contaminated during use it may spread the organism to other quarters and other cows.

Economic importance
The disease is a serious one in that there is extensive destruction of tissue, loss of production, and occasionally death of a cow. Also, there is a possibility that human infection may occur, as the organism may not be destroyed by usual pasteurization procedures.

PATHOGENESIS
The inflammation of the teat sinus and lower parts of the gland suggests invasion via the teat canal. Infection of mammary tissue results in the formation of discrete granulomatous lesions and the development of extensive fibrosis, the spread of inflammation occurring from lobule to
lobule. Infected animals are not sensitive to tuberculin.

When infection occurs early, in the first 15 days of lactation, the reaction is a systemic one with fever and anorexia. At other times the lesions take the form of circumscribed abscesses and fibrosis. There may also be infected loci in supramammary and mesenteric lymph nodes.

**CLINICAL FINDINGS**

Affected animals may show a systemic reaction with high fever, depression and anorexia, but an acute or subacute inflammation is more usual. Fibrosis of the gland and the appearance of clots in a grayish, viscid secretion that also contains small, white particles is the usual clinical picture. The fibrosis may be diffuse but is usually in the form of discrete masses 2–5 cm in diameter. Badly affected glands become grossly enlarged, and may rupture or develop sinus tracts to the exterior. None of these cases recovers sufficiently to justify retention and all are eventually culled.

Laboratory examinations of herds in which cases occur may also reveal subclinical cases that have intermittent flare-ups.

**CLINICAL PATHOLOGY**

The bacteria can be detected on culture of the milk. Small (1 mm diameter) specks are visible in the milk and, on microscopical examination, these prove to be felled masses of mycelia. Herds containing infected cows have been readily identified by culture of bulk milk samples. A gentamicin–blood culture medium has good selectivity. The normal blood agar plates need to be kept for an extended period of time in order to detect growth. Colonies may not appear until 72 hours.

**NECROPSY FINDINGS**

Grossly, diffuse fibrosis and granulomatous lesions containing pus are present in the mammary tissue. The lining of the milk ducts and the teat sinus is thick and roughened. On histological examination the granulomatous nature of the lesions is evident. Metastatic pulmonary lesions have been found in occasional longstanding cases.

**Samples for confirmation of diagnosis**

- Bacteriology – mammary tissue, regional lymph node
- Histology – formalin-fixed mammary tissue for light microscopy.

**TREATMENT**

The disease does not respond well to treatment. Erythromycin and intramammary miconazole are most effective but need to be used for 1–2 weeks.

**CONTROL**

Invasion probably occurs via the teat canal from a soil-borne infection; proper hygiene at milking and strict cleanliness during intramammary infusion are therefore necessary on farms where the disease is enzootic. Treatment in late cases is unlikely to be of value because of the nature of the lesions, and in affected herds particular attention should be given to the early diagnosis of the disease.

**BACILLUS SPECIES**

*Bacillus cereus* and *Bacillus subtilis* are saprophytic organisms and only chance mastitis pathogens; they have been known to cause an acute hemorrhagic mastitis in cattle. *B. cereus* cases are often associated with contamination associated with teat injuries or surgery. The mastitis may also occur in cows at the time of calving and is associated with the feeding of brewers' grains in which the spores of *B. cereus* are present.

The infection is thought to occur during the dry period following the use of dry cow therapy preparations that may have been contaminated with the organism. Infection probably occurs at the time of infusion but the acute mastitis does not occur until after parturition. *B. cereus* is a spore-former and may remain dormant in the mammary gland for long periods, unaffected by the presence of the antibiotic. In one outbreak, 62 of 67 cows infused with a dry cow infusion product contaminated with the organism developed acute hemorrhagic mastitis. Six cows died; the remainder survived but were subsequently culled and slaughtered because of recurrent mastitis, inadequate milk production and loss of weight.

Clinically there is a peracute to acute mastitis affecting one or more quarters. There is severe swelling and pain and the secretions are red-tinted and serous in consistency. Initially there is a high fever (40–41°C, 104–106°F) and severe toxemia. Affected cows are weak and quickly become recumbent; death may occur in 24–36 hours. Gangrene may occur and, in cows that survive, portions of affected gland will slough out and a chronic relapsing mastitis will persist. Experimentally produced mastitis due to *B. cereus* causes toxemia, acute swelling of the quarter and clots in the milk. The mastitis persists in a chronic form and the quarter eventually dries up.

The organism can usually be cultured from milk samples from affected quarters. At necropsy there is focal hemorrhagic necrosis of the mammary tissue, acute lymphadenitis and disseminated intra-vascular coagulation.

Treatment consists of intensive fluid therapy, a broad-spectrum antibiotic intravenously, and vigorous massage and stripping of the affected gland. Intramammary infusion of the most suitable antibiotic determined by culture and sensitivity is indicated but the results are often not good because of the presence of severe hemorrhage and necrosis and plugging of the lactiferous ducts. Prevention depends on the use of sterile techniques during teat surgery and the use of sterile intramammary infusions and instruments. In problem herds, autogenous bacterins have been prepared but not extensively evaluated.

If *B. cereus* infection is identified in the mammary glands of dry cows the recommended prevention program is infusion of each quarter with 750 mg neomycin and 375 mg framycetin.

*B. subtilis* is recorded less frequently as a cause of acute mastitis. Infection is characterized by yellow or bloody milk, sometimes with clots, and the cow is febrile.

**CAMPYLOBACTER JEJUNI**

Only one case has been recorded but the incident is of some importance because of its zoonotic impact. Infection of the udder by the organism is easy to establish and the infection is persistent but subclinical for the most part. Other experimental cases have been recorded and campylobacters that have not been further identified have also been observed in naturally occurring cases. These are characterized by fine granular dots in the milk, very high cell counts and a transient episode of fever and swelling of the quarter.

**CLOSTRIDIUM PERFRINGENS TYPE A**

This is a rare form of mastitis characterized by high fever, swelling, and
superficial hyperemia of the affected quarter, followed later by gangrene, enlargement of the supramammary lymph nodes, a thin brown secretion containing gas, and subcutaneous emphysema. Early treatment with a broad-spectrum antibiotic can be successful, but advanced cases are uniformly fatal.

**FUSOBACTERIUM NECROPHORUM**

This is a rare type of mastitis but is likely to have a high incidence in the herd when it occurs. Mixed infections of *Fusobacterium necrophorum* appear to play an important role in summer mastitis due to *A. pyogenes* (see above). Affected quarters have a viscid, clotty, stringy secretion but there is little fibrosis. No systemic reaction occurs but treatment with a variety of antibiotics is unsuccessful.

**HISTOPHILUS SOMNI**

Histophilus somni (formerly *Haemophilus somnius*) has caused mild, chronic mastitis, an acute form with high fever and blood-stained milk, and a gangrenous form.10,11

**LISTERIA MONOCYTOGENES**

Listeria monocytogenes is being recorded with increasing frequency as a cause of bovine mastitis because of the zoonotic importance of the organism in dairy products. Most cases are subclinical and abnormal milk is rare.12 The SCC is usually greater than $10^7$ cells/mL milk. An ELISA test can be used to detect antibody in milk.13 Culture of bulk milk samples is an adequate means of locating herds with infected cows.14 Over a 23-year period in Denmark, the percentage of cows infected with the organism varied from 0.01–0.1% and that of herds with an infected cow from 0.2–4.2%.15 Typing of the isolates from bovine mastitis and human clinical isolates revealed that 79% of bovine and 48% of human isolates shared common types. Identifying infected cows may not be easy because the mastitis is mild; the milk is normal in appearance but the quarter does lose productivity15 and the milk carries a high SCC. The disease is characteristically unresponsive to treatment with penicillin, although the organism may be sensitive to the antibiotic in vitro tests. The persistence of the clinical signs should arouse suspicion of *L. monocytogenes* as a cause.

**MYCOBACTERIUM SPECIES**

Tuberculous mastitis is described under tuberculosis. Other mycobacteria, especially *Mycobacterium lacticola*, have been isolated from cases of mastitis in cattle that occur after the intramammary infusion of therapeutic agents in oils.16 The disease can be reproduced by the intramammary injection of the organism in oil but not when it is in a watery suspension. Subsequent oily infusions exacerbate the condition. Clinically there is tremendous hypertrophy of the quarter with the appearance of clots in discolored milk, but there is no systemic reaction. Affected animals do not show sensitivity to avian or mammalian tuberculosis. No treatment is effective. It is suggested that the treatment of injured teats and quarters with oil-based intramammary preparations is inadvisable because of the risk of them already being infected with mycobacteria.

A mild, acute mastitis, self-terminating and unresponsive to treatment, has occurred in outbreak form.17 It may be unassociated with intramammary infusion but is apparently predisposed to by stress and associated with an unidentified mycobacterium.

*Mycobacterium fortuitum* is encountered rarely as a cause of a severe outbreak of bovine mastitis. Infected quarters are seriously damaged and do not respond to treatment, and affected cows die or are salvaged.18 The disease can be reproduced experimentally and affected animals show positive reactions to mammalian and avian tuberculosis and some sensitivity to johnin. Similar experiences are recorded with *Mycobacterium smegmatis*19 and *Mycobacterium chelonae*.20 The mammary secretion of affected quarters varies from pus to a watery fluid containing flakes and there is a high milk loss and irreparable damage to quarters. *M. smegmatis* causes hypertrophy of the gland of such proportions that all cases need to be culled.

**SERRATIA SPECIES**

Serratia marcescens causes mild chronic mastitis in which swelling of the quarters with clots in the milk appear periodically. *Serratia* mastitis occurs naturally and has been produced experimentally.19 Penicillin (2 g initially followed by three daily doses of 1 g by intramammary infusion) is a satisfactory treatment. *Serratia liquefaciens* has caused a similar mastitis.22 Most cases are sporadic but herd outbreaks caused by the use of contaminated sawdust as bedding and inadequate cleaning of the teats before milking may occur.23

**FUNGI AND YEASTS**

Trichosporon spp. can cause mastitis in cattle and is manifested clinically by swelling of the gland and clots in the milk. The infection rate is low and the fungi disappear spontaneously. Experimental transmission of the disease has been effected.

Cryptococcus neoformans, the yeast that causes human cryptococcosis, has caused acute mastitis in cattle24 and buffaloes.25 Contaminated infusion material and spread from other infected quarters are the probable sources of infection. Infection in humans drinking the milk is unlikely to occur because the yeast does not withstand pasteurization, but there may be some hazard to farm families. While there is no systemic reaction, the mastitis may be acute, with marked swelling of the affected quarter and the supramammary lymph node, a severe fall in milk yield and the appearance of a viscid, mucoid, gray-white secretion. Clinical mastitis persists for some weeks and, in many cases, subsides spontaneously, but in others the udder is so severely damaged that the cow has to be slaughtered. Systemic involvement occurs rarely. At necropsy, there is dissolution of the acinar epithelium and in chronic cases a diffuse or granulomatous reaction in the mammary tissue and lymph node. Similar lesions have been found in the lungs.

Many other yeasts, including *Candida* spp., *Saccharomyces* spp., *Pichia* spp., *Torulopsis* spp., and *Aspergillus fumigatus* have also caused mastitis in cattle. A survey of 91 bovine cases of fungal mastitis in the USA showed that 78% belonged to *Candida* spp.19 The infection is probably introduced by contaminated intramammary infusions or teat cup liners.26 Establishment of the infection is encouraged by damage to the mammary epithelium and stimulated by antibiotic therapy; for example *Candida* spp. utilize penicillin and tetracyclines as sources of nitrogen.

A fever (41°C, 106°F) is accompanied by a severe inflammation of the quarter, enlargement of the supramammary lymph nodes and a marked fall in milk yield. The secretion consists of large, yellow clots in a watery supernatant fluid. Lesions are limited to the walls of the milk cistern and there is no invasion of the mammary gland itself.27 Usually the disease is benign and spontaneous recovery follows in about a week. In cases of infection by *A. fumigatus* or *Aspergillus nidulans* there are multiple abscesses in the quarter. These are surrounded by granulomatous tissue but the milk ducts are generally unaffected.

None of these infections responds well to antimicrobial therapy but treatment with iodides, either sodium iodide intravenously, organic iodides by mouth, or iodine in oil as an intramammary infusion, might be of value. A number of drugs, including cycloheximide, nystatin, polymyxin B, neomycin, and isoniazid, have been tested for efficiency against mastitis in cattle produced...
experimentally by the infusion of \textit{C. neoformans} but did not alter the clinical course of the disease. Methirolate (20 mL of a 0.1% solution) as an infusion daily for 2–3 days is reported to have a beneficial effect if administered early in the course of the disease. Actinomycotic agents tested in vitro against fungi, mostly \textit{Candida} spp., from cases of mastitis showed sensitivity to clotrimazole, nystatin, polymyxin, miconazole and amphotericin B, and least sensitivity to 5-fluorocytosine. Miconazole (100 mg/L as an intramammary infusion, possibly supplemented by 400 mg doses given intravenously) is reported to produce good results.

Sulfamethoxypyridazine has been successfully treated by concurrent use of nystatin, polymyxin, miconazole and clotrimazole, showed sensitivity to clotrimazole, and has been reported to produce good results.

tank milk SCCs to below 400,000 cells/mL. With good management, the incidence of clinical mastitis can be kept low (7–21 cases/100 cows/year with dairy herds averaging 45 cows/ herd) by culling any cow with chronic or recurrent mastitis and by paying great attention to housing and management standards.6,7

While the rate of contagious mastitis has been decreased with the program, the rate of infections and the incidence of mastitis associated with environmental pathogens such as S. uberis and the coliform bacteria has not decreased.

Approximately 65% of clinical cases are now due to environmental pathogens. Organisms prevalent in the cow’s environment currently cause the most costly types of mastitis in the USA.7

Economic benefits, incentives, and penalties

Mastitis is one of the most costly diseases in dairy herds. Some surveys indicate that the cost incurred by producers because of clinical mastitis is much higher than the cost of prevention.7 An integrated mastitis control program has always been an excellent investment for the dairy farmer, with a revenue to cost ratio of approximately 6:1, most of the additional revenue being due to increased milk production.

Differential payments to farmers for milk quality are also an economic incentive to adopt a control program.6 The widespread adoption of bulk tank milk SCCs as a measure of milk quality, and the adoption of payment schemes of increasing severity, has stimulated farmers to reduce their cell count. Many milk marketing cooperatives have established both penalty and incentive programs based on bulk tank milk SCC and total bacterial counts as global measures of milk quality.

Requirements

The requirements for a successful mastitis control program include a willing farmer, a capable diagnostic laboratory, an enthusiastic and knowledgeable veterinarian, a record-keeping system, adequate milking machinery and adequate housing facilities.

The farmer must have health and production goals and be willing to achieve them by making a commitment to invest the resources to control mastitis. Wide variations in the costs of controlling and monitoring mastitis in herds are evident because of lack of client compliance with accepted recommendations for mastitis control.8 There are also variations in the level of mastitis control procedures adopted by producers, which affect the success of a program. A survey of a large number of dairy herds in Ohio revealed that most herd managers teat dipped all cows after milking and used dry cow therapy.9 However, other mastitis control practices were not as widely adopted. In addition, those herds classified as negative for contagious pathogens used predipping compared with herds classified positive for contagious pathogens, which did not. Predipping was also associated with a number of management factors, including having a clean and dry environment for the cows, cows with clean udders and teats, and minimal use of water in the milking parlor. A survey of Ontario dairy farms indicated that only one-third of producers used all five of the recommended mastitis control practices.10 Lack of adoption may result from a lack of awareness of the economic returns from a complete program, adoption of a new practice only in response to a problem, or competition for liquid financial resources from other aspects of the enterprise.

The veterinarian must be knowledgeable about all aspects of mastitis and be willing to invest the time and effort required to provide sound advice based on the health and production information obtained from monitoring the herd. Some surveys of veterinarians indicate wide variations in their clinical approach to cases of mastitis in the field.11 Many factors of importance for the clinical diagnosis of mastitis were not considered.

A data recording system that records all the udder health and production data, and the milk quality of each cow and the herd on a regular basis is a vital requirement. A diagnostic laboratory or milk recording agency that provides regular SCCs of individual cows is necessary to monitor udder health. The milking machine and the housing facilities must be adequate for the size of the herd. The animal attendants must be aware of the health and production goals of the herd and adhere to the principles of mastitis control.

OPTIONS IN THE CONTROL OF MASTITIS

The broad options for control are either eradication or decreasing the infection rate, and either legislative control or implementing a voluntary program.

Eradication

Complete eradication of bovine mastitis from a herd or geographical region is not a practicable target in most circumstances. The exception is mastitis due to Streptococcus agalactiae, which can be eradicated from individual herds by a blitzen technique. The difficulty in attempting to eradicate mastitis is that the contagious causes of mastitis, S. agalactiae and Staphylococcus aureus, are so contagious, and the sources of infection so widespread, that adequate quarantine would be very difficult to maintain. In the case of S. aureus there is the additional difficulty of eliminating the infection from its intracellular sites in mammary tissue. The environmental infections, especially Escherichia coli, pose an even greater problem. They are so ubiquitous that reinfestation would be almost immediate in cows housed in economically practicable surroundings.

Decreasing the infection rate

This is a practicable proposition, the degree of limitation being dependent on the need to maintain cost-effectiveness. One of the virtues deriving from this necessity is the concept that subclinical mastitis causes a continuous low-level leukocytosis in the milk that acts as a protective mechanism against other infections. Present-day knowledge about immunity in the mammary gland suggests that control programs that reduce milk SCCs to unrealistically low concentrations may reduce the gland’s resistance to clinical mastitis. Correspondingly, the complete elimination of common udder pathogens such as S. agalactiae and S. aureus is thought to increase the susceptibility of the udder to environmental pathogens, especially the coliforms. Another relevant example is the commonly encountered minor pathogen Corynebacterium bovis, which may be a significant microbial agent in maintaining the resistance of udders. The mastitic effect of this organism is too low to warrant action against it but the infection rate with major pathogens is significantly lower in quarters that harbor it than in those that do not.12 An intensive program to disinfect udders could well eliminate C. bovis and increase susceptibility to other pathogens. There is good field evidence to suggest that this is in fact happening in North America and the UK. C. bovis is likely to be more important where cows are housed, or confined in straw yards, and therefore more exposed to teat contamination with coliforms. The criticism relates to the increasing numbers of clinical cases, often associated with Gram-negative organisms, that occur in herds that have achieved very low levels of udder infection, as indicated by very low bulk milk cell counts. The question of whether it is better practice to maintain some level of bacterial infection with innocuous organisms in the udder as a protection against more damaging pathogens, rather than to attempt complete bacterial sterilization, is still unresolved. For the time being it is generally agreed that decreasing the infection rate is the appropriate target.

Legislative control

Mastitis does not lend itself to eradication (as set out under Eradication above) and...
so legislative control of the disease is not attempted.

A voluntary program
Most of what is done in mastitis control is by voluntary involvement by producers in programs aimed at reducing the incidence of mastitis and maintaining the infection rate at a low level. The justification for control of the disease is purely economic, and a control program must therefore be based on its applicability on each individual farm or area. National control can only be in the form of providing incentives by educational and laboratory assistance to individual farmers who wish to participate. The value of a mastitis awareness program, and the part played by the two-way flow of information between farmers and the program operators is most apparent when an area campaign is conducted by a government or industrial sponsor. Once a control program is in place it is customary for milk processors, aided in some places by government agencies, to encourage participation by paying incentives for bulk tank milk with low SCCs or bacteria counts, or refusing to accept milk for processing or, in some cases, refusing to transport milk that does not satisfy statutory requirements. This could be the first step in incorporating the program into planned health and production programs that promote mastitis control and maintenance of milk production at financially optimal levels. Mastitis infections in beef cattle herds are currently at too low a level for a mastitis control program to be financially advantageous.

PRINCIPLES OF CONTROLLING BOVINE MASTITIS

Dynamics of infection
The principles of a bovine mastitis control program are based on changing the dynamics of infection, which are as follows:

Prevalence of infection is a function of the rate of new infection minus the rate of elimination
Rate of new infection is a function of the level of exposure times the number of susceptible quarters
Rate of elimination is a function of the number of infections times the efficacy of treatment plus spontaneous cure.

Successful control occurs when the level of infection is held low or is decreased, either by preventing new infections or eliminating existing infections.

The dynamics are not, however, so simple in reality. They vary with the susceptibility of the individual animal, which changes with age and stage of lactation and is season-dependent. The dynamics may vary with the pathogens involved, and the relative importance between herds can be very considerable and also vary with time. The duration of infection may be extremely different for different pathogens. E. coli causes mild to severe acute clinical disease but usually self-elimates quickly; it is rarely found in subclinical infections. S. agalactiae and S. aureus are very persistent, and S. aureus responds poorly to treatment. The rate of elimination and the persistency of these pathogens are highly variable. Similarly, there can be large variations in the rate of new infections, which is very much related to the identifiable risk factors, including rate of teat contamination, mechanisms aiding teat penetration, and effectiveness of establishment and growth of bacteria in the mammary gland.

The success of a control program can be measured by the decrease in level of infection and the speed with which this is achieved. The farmer must be able to appreciate progress within a year in order to remain enthusiastic about application of the methods. The level of infection can be controlled significantly by lowering the rate of new infections, but the speed of change very much depends on the duration of the infection and is thus related more to the rate of elimination. No control procedures are available to prevent all new infections and only culling of chronically infected cows is absolutely successful in eliminating infections. Control schemes therefore require both prevention and elimination to give optimal effect, and that optimum will vary with each pathogen.

The specific components of a mastitis control program must be devised to fulfill three basic principles, which are to eliminate existing infections, prevent new infections and monitor udder health.

1. ELIMINATE EXISTING INFECTIONS
   The control program must reduce the duration of infection in the cows. Antimicrobial therapy during the dry period is the best method of achieving this objective. Treatment during lactation can be useful to eliminate some existing infections, depending on the causative agent. Culling of chronic cases that are not eliminated with dry period treatment is also used to remove the most persistent existing infections. Further study needs to focus on development of treatment protocols and on cowside identification of the causative bacterial agent.

2. PREVENT NEW INFECTIONS
   The control program must reduce the rate at which new infections occur. The dipping of all teats in an effective teat dip after each milking is the best method of reducing the new infection rate. Insuring that the milking machine is functioning properly and used correctly will result in less spread of infection. The dry period is the time of greatest risk of new infection, and blanket dry cow therapy or application of an internal teat sealant is efficacious in preventing new infections during the dry period. Environmental and nutritional management have also become important for the prevention of new infections. Specific recommendations for methods of reducing new infection rate depend upon the predominant pathogen in the herd.

3. MONITOR UDDER HEALTH STATUS
   An ongoing program to monitor the udder health status of individual cows as well as the herd is needed to evaluate the effectiveness of the control efforts. Monitoring methods should also assist with specific decision-making, such as optimized treatment protocols or culling. In the five point mastitis control programs recommended by the NIRD and the NMC, monitoring was not emphasized. As udder health status improves, and as milk quality premiums and penalty programs become meaningful, there is a need to continuously monitor udder health.

MASTITIS CONTROL PROGRAMS

A major step forward in mastitis control occurred in 1970 with the publication of the results of controlled field studies carried out by the NIRD. The five-point control plan was based on attacking the key areas in the dynamic processes of mastitis and the individual components of the plan were evaluated as efficacious by field testing in dairy herds. Its success has been well documented. The five-point plan has been highly successful for the control of contagious mastitis but is not adequate for environmental mastitis. The plan depends heavily on the motivation, education and financial commitment of the milkers and the herd owner to achieve good and consistent results.

The five-point mastitis control program is as follows:

1. Udder hygiene and proper milking methods
2. Proper installation, function, and maintenance of milking equipment
3. Dry cow management and therapy
4. Appropriate therapy of mastitis cases during lactation
5. Culling of chronically infected cows

Five additional management practices are recommended to make a ten-point mastitis control program, which includes emphasis on an appropriate environment, particularly for the control of
environmental mastitis, and the keeping of records, monitoring udder health and setting goals for udder health status.

6. Maintenance of an appropriate environment
7. Good record keeping
8. Monitoring udder health status
9. Periodic review of the udder health management program
10. Setting goals for udder health status.

The ten-point mastitis control program satisfies the basic needs of the farmers, an essential prerequisite in the implementation of a voluntary program. The program is profitable, within the scope of the producer’s technical skill and understanding, capable of being introduced into current management systems, and encourages farmers to continue the program by rapidly reducing the occurrence of clinical mastitis and the rejection of milk by milk processors on the grounds of quality.

The components of the recommended ten-point mastitis control program are the same for all situations. The exact level of severity at which it will be implemented depends on its cost-effectiveness; higher milk and cattle prices will justify higher financial inputs. The program has the virtues of simplicity, profitability and widespread applicability, and most countries with a significant dairy industry have devised their own variant of it to suit their own local needs, especially the targets of freedom from infection and other quality-control criteria. The ten-point program was designed primarily for the control of the common contagious mastitis pathogens and may encounter difficulties unless measures to control the environmental infections receive special attention.

THE TEN-POINT MASTITIS CONTROL PROGRAM

1. UDDER HYGIENE AND PROPER MILKING METHODS

The principles of a proper milking procedure include:
- Premilking udder hygiene
- Stimulation of milk letdown
- Efficient removal of the milk
- Postmilking teat disinfection.

These principles are important for controlling the spread of contagious pathogens and for preventing new intramammary infections associated with environmental organisms. There is much farm-to-farm and region-to-region variation in how these milking procedures are applied. Milking methods are often taught to milkers by observation of the current methods used on the farm, and milkers are seldom objectively evaluated, especially in family farm operations with only one or two farm employees.

Several important steps are necessary in establishing a milking management routine, including the following.

Establish and maintain a regular milking schedule in a stress-free environment

A management routine using twice-daily milking should strive for a 12-hour interval. In the same way, an 8-hour interval between milkings is necessary for thrice-daily milking. The milking schedule is obviously less important with robotic milking. Consistency is as important as maintaining these exact intervals. Any influence that may add stress to the milking environment is to be avoided. For example, harsh crowd gates, rough handling, barking dogs and people shouting can be associated with epinephrine release, which will counteract the effect of oxytocin for efficient milk letdown.

Insure that teats are clean and dry prior to milking

The major objective of premilking udder preparation and teat sanitation is to reduce the microbial population of teat skin, and particularly at the teat end. The aim of these techniques is to minimize the probability of new intramammary infection and have good milking performance. Milking time hygiene is extremely important because of the potential interaction between milking machine function and the microflora of teat skin. The incidence of intramammary infection is highly correlated with the number of mastitis pathogens on the teat end at milking.

Premilking cow preparation

Premilking cow preparation is a step in milking management where there is considerable variability between what is recommended and what is actually practiced. The goal is to milk clean and dry teats. Current recommended procedures for premilking udder preparation range from waterhose washing and manual drying of teats, to washing teats with a paper towel wetted in warm sanitized solution plus drying with a single service paper towel, to the use of premilking teat dipping in germicide plus paper towel drying. The additional step of premilking teat disinfection (predipping) has been incorporated as part of the milking routine on many dairy farms. It is argued that manual teat washing improves stimulation and the release of oxytocin for milk letdown, in addition to cleaning debris from the teats and teat ends. However, with properly functioning milking equipment, there is little evidence that the manual massage is necessary for good milk letdown. In milking parlors where hand-held spray washers are used, it is important to avoid wetting the udder. Excessive water use can lead to bacterial contamination of the teat cups, and to an increase in the incidence of mastitis. In addition to individual paper towels, the use of latex gloves is also recommended in order to minimize cow-to-cow contamination.

Udder hygiene score

An udder hygiene scoring system has been developed, with the udder being viewed from behind. Score 1 is an udder free of dirt, score 2 has 2–10% of the surface area dirty, score 3 has 10–30% of the surface area covered with dirt, score 4 has more than 30% of the surface area covered with caked on dirt. A hygiene scoring system is repeatable and easy to use, but only hygiene scores for the udder and hind limbs were associated with cow composite milk SCCs.

Premilking teat disinfection

Premilking teat disinfection, more commonly referred to as predipping, is used by some dairy producers as a component of a mastitis control program. Premilking teat disinfection with chlorhexidine in association with good udder preparation and postmilking teat disinfection can further reduce the occurrence of new intramammary infections during lactation. The use of a 0.25% iodine premilking teat disinfectant is more effective against major pathogens than postmilking disinfection only. The use of predipping is increasing as the predominant cause of mastitis shifts from contagious pathogens to environmental pathogens. Controlled studies on the effectiveness of predipping indicate significant merit in the use of iodine predipping for the reduction of udder infections due to environmental pathogens. Some studies found that premilking teat dipping with 0.25% iodophor did not reduce the incidence of clinical mastitis due to environmental pathogens and the use of 0.5% iodophor plus good udder preparation did not affect the prevalence of infection of coagulase-negative Staphylococcus spp., but the rate of clinical mastitis in the control group was 1.38 cases per 1000 cow-days compared to 1.06 cases per 1000 cow-days in the predipped group. The benefit–cost ratio of 0.37 indicated that the benefit of reduced incidence of clinical cases of mastitis did not justify the added expense required to predip the herd.

Although premilking teat dipping with iodine-based sanitizers may play a role in reducing new intramammary infections, there are some precautions that should be...
taken. The major concern is the potential for increased iodine residues in milk. Predipping with either 0.5% or 1% iodophor does not significantly increase milk iodine residues if a paper towel is used to dry the teats. Without drying, iodine residues are significantly increased. In addition, predipping in combination with post-milking teat disinfection may increase the potential for residues.21

Implementation of predipping into the cow preparation methods may require significant management changes, such as the drying of teats. Some of the improvement inudder health associated with the implementation of a predipping program may be attributable simply to the milking of clean, dry teats. Prior to the commencement of predipping, attaching the unit to wet or dirty teats may have been common. Whatever management methods are adopted on a particular farm, premilking hygiene and udder preparation can have a significant effect on milk bacterial counts, and on the incidence of mastitis.20 The overall objective is to have clean and dry teats ready for attachment of the milking unit.

Check foremilk and udder for mastitis
Early clinical mastitis can be detected by physical examination of the udder for swelling, heat or pain, and by using a strip cup or black plate to examine foremilk from each quarter of each cow prior to every milking. This step has been a standard NMC management recommendation but the supporting evidence has been inconsistent. The rate of implementation of foremilking stripping is widely variable and depends upon the management system used being used more commonly in milking parlor situations.

Checking foremilk has three major advantages:
- Detection of clinical mastitis (such as clotty, stringy or watery milk), as early as possible. Detection of abnormalities is enhanced if the milk is evaluated against a dark surface such as a black strip plate
- Forestripping theoretically aids in preventing new infections of the mammary gland by flushing pathogens from the teat streak canal prior to milking. Bacterial colonization of the teat canal may not represent a problem until the organisms gain access to the teat sinus beyond the rosette of Furstenburg
- Stimulation of the milk letdown process. This could be helpful in systems where minimal cow preparation is used, such as a premilking program consisting of only a dry wipe.

In tie-stall barns, a strip cup is necessary to avoid contaminating the stall bedding or the cow herself. In milking parlors, it is common to use the concrete floor surface for detection of abnormalities in the milk. In either case it is important to recognize the potential for cow-to-cow transmission of pathogens by milk contact from one teat to another. For this reason, forestripping is often implemented prior to the predipping or udder washing step.

Attach the milking unit properly
The milking unit teat cups should be carefully attached to the udder within 90 seconds of starting udder preparation. The milk letdown process that follows the release of oxytocin after udder stimulation is at maximum for 3-5 minutes. Some effects of the oxytocin may last up to 8 minutes. It is important to use this physiological event to its maximum for the most efficient removal of the milk. The proper timing of milking unit attachment has been shown to shorten milk-out time and increase lactation productivity. However, consistency in the time interval from stimulation to attachment of the unit is as important as the exact time.

When attaching the teat cups, it is imperative to minimize the amount of air drawn into the system. Excessive air inlet could result in vacuum fluctuations, which may predispose to milk aerosol impacts of the teat end and machine-induced infections.

The machine position and support should be adjusted as necessary during milking. This will ensure that quarters milk out properly. The milking unit should hang on the cow as straight and level as possible. Improperly adjusted support could contribute to uneven milk-out, and to an unbalanced udder on some cows; in addition, there is an increased probability of liner slips and squawking, which in turn will increase the risk of new intramammary infections. The mechanics and importance of liner slips will be discussed with milking machine function later in this chapter.

The use of proper milking machine attachment and adjustment methods affects the number of milker units that can be efficiently handled per person. With a tie-stall barn pipeline milking system it is recommended that a maximum of three units per person be used. It is unlikely that producers who milk with more than three units in a tie-stall barn are using appropriate cow preparation and milking machine attachment methods.

Minimize machine stripping and avoid liner slips
The majority of milking-machine-induced intramammary infections occur near the end of milking. Liner slips occur with a greater frequency near the end of milking. During a liner slip, air sneaks between the teat and liner (heard as a squawk), increasing the potential for small droplets of contaminated milk to be propelled backwards against the end of the other teats (teat end impacts). Over a sustained period of time, liner slips and milk impacts may result in an intramammary infection.

Machine stripping is the act of putting hand pressure on the milker unit at the end of milking, for the purpose of removing extra milk. Machine stripping is habit forming, and will eventually lead to increased milking time. It also increases the risk of squawking, liner slips and milk impacts.

Avoid overmilking or removing the unit under vacuum
As soon as a cow is milked out, the vacuum to the milker unit should be shut off and the teat cups should be removed. The milker unit should gently fall off the teats, causing no irritation. Removing the unit under vacuum will cause milk and air to impact on to the teat ends. Overmilking should be avoided to prevent teat end irritation. The unit should be removed as soon as the first quarter is milked out. The risk of liner slip is also increased during overmilking but there is little evidence that overmilking will result in an increased rate of intramammary infection, unless liner slips and teat end impacts occur. The practice of removing teat cups individually is also discouraged.

Use an effective and safe postmilking teat germicide after every milking
Teat dipping or spraying with a germicidal solution immediately after every milking is an effective milking management practice to reduce the rate of new intramammary infections. Postmilking teat antisepsis is regarded as the single most effective mastitis control practice in lactating dairy cows.

Teat dipping is a simple, effective and economical means to reduce bacterial populations on teat skin. There is general agreement that the numbers and types of bacteria on teat skin have a direct relationship to the incidence and types of intramammary infections that develop in a herd. An effective teat dip, correctly used, will reduce the incidence of new udder infections by 50-90%.

There are several major classes of postmilking teat sanitizer, and many available products within each class. The classes of product vary widely in their composition, formulation and mode of action. Each product should be evaluated for its safety, efficacy, advantages and disadvantages. The most commonly used
Teat dips in the USA and Canada fall into several major classes.

Iodophor formulations
Iodophor teat dips have been used extensively and marketed in a variety of formulations, ranging from 0.1–1.0% available iodine. The safety and efficacy of these products are well established.\(^2\)

Chlorhexidine
Chlorhexidine teat dips are also widely used and effective for reducing new infections.\(^2\) They are more efficacious in the presence of organic material than other classes of product. Chlorhexidines have a broad spectrum of antimicrobial activity and excellent persistence on teat skin.\(^1\) Commercial preparations are formulated with a dye to make the product visible, and with glycerine to minimize teat skin irritation.

Linear dodecyl benzene sulfonic acid products
Linear dodecyl benzene sulfonic acid (LDBSA) teat dips contain an organic acid and are formulated with emollients. They are generally nonstaining, tolerant of organic matter and less irritating than most other products; their efficacy against major mastitis organisms is well established.

Quaternary ammonium compounds
A variety of quaternary ammonium chemicals, in combination with lanolin or glycerine, are available as teat dip germicides and are safe and effective. They are readily broken down in the environment and depend heavily upon proper formulation for effectiveness.

Sodium hypochlorite
Many dairy farmers prepare their own teat dip by dilution of commercial laundry bleach to a final concentration of 4% sodium hypochlorite. It is effective and extremely low-cost. However, these dips are not government approved, have a strongly disagreeable odor, and can be inactivated by organic material. There is also a risk of mixing errors, resulting in the potential for irritation of teats and milkers’ hands.

External teat sealants (barrier teat dips)
A goal that has yet to be achieved is development of a barrier teat dip that provides an effective teat sealant for use in lactating cows and withstands environmental contamination but is easily removed with minimal premilking udder preparation. Latex and acrylic latex-based products have been developed to act as a physical barrier to the entrance of mastitis pathogens into the udder. These products were aimed at the prevention of coliform mastitis. However, it has proved to be difficult to remove the residual product from teats. Furthermore, the barrier product alone is not intended to be effective against other major mastitis organisms.

External teat sealants have been formulated in combination with disinfectants to provide protection as both a barrier and a germicide. A postmilking teat disinfectant containing 0.64% sodium hypochlorite in a gel formulation was an effective and safe teat dip preparation.\(^2\) However, in experimental studies, barrier teat dips were no more efficacious in preventing new intramammary infections due to \(S.\) \textit{aureus} and \(S.\) \textit{agalactiae} than no teat dip or the use of a nonbarrier product.\(^4\) In contrast to their current use in lactating dairy cows, external and internal teat sealants are being increasingly applied at dry-off (see Dry cow management and therapy, below).

Selection and use of teat disinfectants
With the extensive array of commercially available postmilking teat germicidal preparations, producers need some guidelines in order to make an appropriate selection for use on their farms. Manufacturers of teat dips should provide the producer with documentation of the efficacy and safety of each product. In the USA, teat dip products must be listed with the Food and Drug Administration (FDA). The FDA regulates teat dips for compliance with label accuracy and manufacturing quality, but efficacy data is not required for registration. In Canada, teat dips must be approved by the Bureau of Veterinary Drugs. This approval process requires extensive data on human safety, animal safety and the efficacy of each new teat dip submission. Standard protocols have been endorsed for the evaluation of teat dip efficacy under conditions of experimental challenge with mastitis pathogens, as well as under conditions of natural exposure in commercial dairy herds.

In the USA, iodine-based teat dips are the most commonly used product for postmilking disinfection, and an iodine-based teat dip in 10% glycerin is generally regarded as the gold standard teat dip against which all other teat dips are compared. Dairy producers should request information on effectiveness when selecting a teat dip. Veterinarians should assist producers with interpretation of the data. There is no evidence that changing teat dips on a regular basis is necessary to prevent the development of resistant mastitis bacteria. Monitoring several measures of udder health status will signal the need for a change in teat dip product. The teat dip selected must be compatible with other chemical preparations used in the milking management system.

Postmilking teat dips can be applied by dipping or spraying. In North America, dipping has been the most popular method. However, with the increase in herd size and parlor automation, there is an increase in the use of teat spraying. Spray and dip application of the same product result in equal efficacy, when done appropriately; however, it is easier to do a bad job of teat coverage with spraying than dipping. Under field conditions, the effectiveness of either method will depend upon adequate coverage of each teat. A general recommendation is that as much of each teat should be covered as is possible, and no less than the lower half.

Teat dips should be stored in a cool dry place and not allowed to freeze. Contamination should be prevented, and expiry dates observed. For economic reasons, producers are tempted to dilute commercially available products; however, their effectiveness and safety may not be maintained. At the end of milking, unused teat dip solution should NOT be poured back into the original container. Dipping devices should be cleaned regularly.

In cold weather conditions, precautions should be taken with respect to teat dipping. Dipped teats should be allowed to dry before cows are exposed to cold and windy conditions. This will minimize the occurrence of frostbite of wet teats.

Establish milking order and segregation programs
In herds with a significant prevalence of contagious pathogens, such as \(S.\) \textit{aureus}, establishing a specific milking order may be helpful to limit the rate of new infections. This is a popular veterinary recommendation that is difficult to implement because it usually requires massive disruption of the milking procedure. In general, first-lactation heifers and fresh cows should be milked first. Cows with high SCCs, chronic clinical mastitis and current clinical cases should be milked last. The maintenance and management of both SCCs and clinical mastitis records becomes important to make milking order programs work.

In larger herds, cows are usually grouped according to stage of lactation and production level. For nutritional management reasons, it is often suggested to have high-, medium- and low-production groups. In herds with a high prevalence of \(S.\) \textit{aureus} mastitis, it has been suggested that the problem of spread would be stopped by simply isolating infected cows and milking them last. In theory, segregation combined with culling and effective dry cow management should allow the prevalence of \(S.\) \textit{aureus} to approach zero. However, the change in prevalence of \(S.\) \textit{aureus} infection in unsegregated herds compared with
herds using a segregated program indicates no significant difference. A more significant decrease in prevalence of S. aureus mastitis was found in herds that gave priority to a full milking hygiene program, in combination with dry cows therapy and culling. Segregation is not a simple, stand-alone solution to contagious mastitis problems.

Disinfect teat liners
Disinfection of the milking machine teat cup liners between cows has the potential of limiting the spread of contagious organisms from cow to cow since bacterial populations in liners can be greatly reduced by sanitization. However, there is considerably less documentation that flushing liners will result in major reductions in contagious mastitis problems.

In tie-stall milking barns, liner dis-infection is a laborious process that involves dipping the claw in a series of solutions. Liners must be put through a rinse, a disinfectant and another rinse to remove the germicide. The solutions should be kept hot and replaced when they become overly contaminated. Only two liners can be dipped at one time if the milk hose remains connected to the pipeline, in order to avoid an air lock in the claw, which will reduce the disinfection process. However, if the milk hose is disconnected from the milk pipeline, then all four liners can be dipped at one time. Even with these limitations, dairy herds with intensive management, utilizing individual cow SCCs and culture information, can effectively use liner sanitization to limit the spread of contagious pathogens. Electric hot pails are commercially available in order to maintain the disinfection solution at a sterilization temperature.

In large milking parlor operations, automatic backflushing of milking units between cows is commercially available but expensive to install. In conjunction with automatic take-offs, the claw is flushed with rinse water, followed by disinfectant, and again rinsed, immediately after the unit detaches from a cow. An alternative procedure (cluster dunking) involves back flushing the milking units with water until a clear stream is obtained and then dunking the milking units in a bucket containing disinfectant while avoiding trapping of air in the dunking process. Large numbers of pathogens can be removed from teat cups by the backflushing process but documented reductions in the new intramammary infection rate are not available. For instance, backflushing decreased the numbers of staphylococci and gram-negative bacteria on liners by 98.5% and 99.5%, respectively, caused a small decrease in the number of new infections by C. bovis, but had no effect on the incidence of new infections by staphylococci, streptococci or coliforms. Until backflushing has been demonstrated to decrease the new infection rate, the procedure cannot be a routine recommendation.

2. PROPER INSTALLATION, FUNCTION AND MAINTENANCE OF MILKING EQUIPMENT
The milking machine plays an integral role in the efficiency of the operation of a dairy farm, and it has direct contact with teat tissue. It must perform properly and consistently, twice or three times a day (or much more frequently in robotic milkers), day after day, year after year. For these reasons, it is important that the milking system is installed according to approved guidelines. Regularly scheduled maintenance should be carried out, and machine function should be evaluated by periodic analysis of the system. All persons in the milking management process should thoroughly understand the basic components, function and operation of the milking equipment. They should also be aware of the significance of regular equipment maintenance and of the importance of good milking techniques.

Milk ing system function and objectives
The milking system performs several basic functions to achieve its objectives. These are:

- Causing milk to flow from the teat by exposing the teat ends to a partial vacuum
- Massaging the teat in an effort to relieve the effects of a continuous milking vacuum
- Protecting the milk from contamination while it is transported to a storage device, which cools and stores the milk until it can be transported to the processing plant.

Components of a milking system
In order to carry out the basic functions and to achieve the objective of efficient removal of the milk with minimal opportunity for intramammary infection, milking and milk handling equipment requires three basic components. These are:

- A vacuum system
- A milk pipeline system
- A bulk milk tank for milk cooling and storage.

Considerable engineering expertise goes into the proper design, installation and function of milking equipment. For the purposes of understanding the basic principles of machine milking, a brief description of these three components will be provided.

The vacuum system
Vacuum pump
The function of milking equipment depends upon the creation of a partial vacuum. A vacuum pump is used to continuously remove some of the air from the various lines in the milking system. The amount of air removed determines the system vacuum level, which is important for proper function. The vacuum level is monitored using a gauge which is read in either kilopascals (kPa), millimeters of mercury (mmHg) or inches of mercury (in.Hg). If one-half of the air is removed from the system, the vacuum gauge will read 50 kPa (15 in.Hg). Vacuum pumps are rated on the basis of the volume of air they can move when the intake vacuum is at 50.7 kPa (15.0 in.Hg). Cubic feet per minute (CFM) is the standard air flow measurement. The CFM rating of a vacuum pump determines the number of milking units that can be used on the system. For example, in order to operate six units, the minimum vacuum pump capacity is 52 CFM.

Vacuum reserve tank
Since the vacuum pump continuously removes a constant amount of air from the system, a vacuum reserve tank is placed between the pump and the vacuum supply line. The purpose of this tank is to provide a common site for connecting the vacuum header lines and to provide a reserve of vacuum to help buffer the sudden admission of air into the system. For example, when a milking unit falls off a cow, there should be enough reserve vacuum to maintain the system function. The amount of reserve vacuum needed in a system is a function of pump capacity, pump performance, regulator operation and the degree of system leakage. Vacuum reserve tanks are usually constructed of PVC plastic and should not be less than 75 L capacity.

Vacuum regulator
A vacuum regulator or controller is an important component of the vacuum system. The function of the regulator is to keep the vacuum of the milking system at a preset level by responding to changing air admissions into the system. The regulator should be located in proximity to, or directly on, the vacuum reserve tank. The regulator should be sensitive, for a rapid response to changes in vacuum. Servo-diaphragm regulators are the most sensitive style available, and are highly recommended. An increase in vacuum pump capacity cannot compensate for poor regulator function. Likewise, a sensitive regulator cannot compensate for a deficiency in pump capacity. The two components must work well together.
It is recommended that two vacuum gauges be installed in the system, for the purpose of monitoring the system vacuum. One gauge should be located on the milking vacuum supply line, near the regulator. A second gauge is best situated at the far end of the vacuum pulsation line. A portable mercury manometer should be used on a regular basis to calibrate the accuracy of the system vacuum gauges, as well as to make adjustments to the vacuum regulator. The preferred vacuum system installation consists of two header lines from the vacuum reserve tank, continuing to form a completely looped pulsation line. The recommended vacuum lines are 76 mm diameter PVC pipe, adequately supported, slightly sloped in the direction of air flow, and with automatic drain valves. This line allows for attachment of the milking unit pulsators.

Pulsation system

A properly functioning pulsation system is critical to teat and udder health. The pulsator causes the chamber between the teat cup shell and the liner to alternate regularly from vacuum to air source. Pulsators are either electromagnetic or pneumatic. In an electromagnetic system, all pulsators function together off an electrical signal. An electronic control circuit turns current on and off to the electromagnet. Pneumatic pulsators run off the vacuum system, and use air to move a plunger or slide valve to cover and uncover the air passage, producing the pulsating action.

An understanding of the dynamics within the teat cup and the characteristics of pulsation is crucial to ensuring that the objectives of mechanical milking are achieved. The chamber between the teat cup shell and the liner is regularly subjected to a vacuum source, whereas the inside of the liner is under stable milking vacuum at all times. The pulsation cycle involves a milk phase and a rest or massage phase. When air is admitted between the shell and the liner, the liner collapses around the cow's teat. The collapsed liner has a massaging action on the teat; this is called the rest or massage phase. Milk does not flow from the teat during this phase. When the pulsator opens, the space between the liner and the shell is exposed to system vacuum. This creates equal pressure on both sides of the liner, causing it to open. The cow's teat is now exposed to milking vacuum. This vacuum, in combination with the internal pressure of milk left within the cow's udder, causes milk to be drawn out through the teat stalk canal. This component of pulsation is called the milk phase. The process of pulsing involves repeatedly opening (milk phase) and closing (rest phase) the teat cup liner.

The pulsation cycle is measured by the time, in seconds, for the completion of one milk phase and one rest phase. The pulsation rate refers to the number of cycles completed by a pulsator in one minute. Pulsation rates range from 45–60 cycles per minute. The pulsation ratio is the length of time in each cycle that the pulsator is in its milk phase compared to its rest phase. A common pulsation ratio is 60:40, indicating that in each pulsation cycle the teat cup chamber will be milking 60% of the time and massaging the teat 40% of the time. Wide pulsation rates can speed up milking time but can put undue stress on the teats and teat ends from insufficient rest, predisposing to new intramammary infections.

Pulsation phase refers to the method of pulsation for the whole milking unit, and is either simultaneous or alternating. In simultaneous pulsation all four teat cups milk at the same time and rest at the same time. With alternating pulsation, two teat cups milk while two teat cups rest, then alternate to complete the pulsation cycle. The alternating action may be from side to side, or from front to rear. Alternating pulsation has several advantages. It allows a more uniform milk flow into and out of the claw, which helps to minimize flooding of the claw, which can result in fluctuations in teat end vacuum. In addition, front/rear alternating pulsation allows for a wider pulsation ratio on the rear quarters, which encourages a more uniform and timely milk-out of all four quarters. For alternating pulsation systems with two different ratios, care must be taken to ensure that air hoses are not reversed when attached to the claw.

Electromagnetic pulsators are unaffected by environmental temperature and can function at a constant preset pulsation rate and ratio. Pneumatic pulsators can be greatly affected by changes in temperature and system vacuum. They require more maintenance and constant checking of the settings. Thus, electromagnetic pulsators using alternating pulsation are most commonly recommended, particularly for high-producing cows with fast milk letdown.

If a teat cup is not positioned properly on a teat, the liner may slip down the teat. If a teat cup is not positioned properly on a teat, the liner may slip down the teat. This component of pulsation is called the milk phase. The process of pulsing involves repeatedly opening (milk phase) and closing (rest phase) the teat cup liner.

Repeated teat end milk impacts, particularly with milk contaminated by mastitis pathogens, can result in new intramammary infections.

The milk transport system

Milking parlors and stanchion barn pipelines have similar systems for transporting milk from the cow to the bulk tank. The components of the transport system will be described in the direction of milk flow. The rubber or silicone insert in each teat cup is referred to as a liner or inflation. The liner should milk cows safely, with a minimal number of squawks from downward slippage, and without the teat cup crawl action of riding up on the teats to the base of the udder. Liner performance depends upon many interrelated characteristics of the milking system. Narrow bore liners are recommended. Liners must be compatible with the teat cup shell. The most important management consideration with respect to teat cup liners is to ensure regular replacement, as recommended by the manufacturer. As a general guideline, natural rubber liners last 500–700 cow milkings, synthetic rubber liners 1000–1200 cow milkings and silicone liners 5000–10 000 cow milkings. The desired milking inflation replacement interval (in days) can be calculated using the following formula:

\[
\text{Number of days between changes} = \left(\frac{\text{Number of cow milkings}}{\text{set of liners}}\right) \times \left(\frac{\text{Number of units}}{(\text{Number of cows milking}) \times (\text{Number of milkings/day})}\right)
\]

Other rubber parts of the unit, such as the short air tubes on the claw, should be constantly checked for cracks or signs of wear. These problems could seriously affect air flow and liner pulsation. Proper storage in dark, cool conditions, as well as the correct use of cleaners and sanitizers, can affect the life of rubber parts.

The milk claw

The milk claw is an important component of the milking unit. The claw is the collection point for milk from the four teat cups and should have adequate capacity to handle peak milk flow without flooding. Each claw should have a means of shutting off the vacuum to the teat end, so that the unit is not removed under vacuum. Most claws have an air vent in the upper half to allow a predetermined quantity of air into the unit to facilitate milk flow away from the cow and into the pipeline. Claws should routinely be inspected for cleanliness, plugged air vents and dented liner connectors.

A long milk hose is used to carry milk from the claw to the pipeline. The hoses can be made of plastic, rubber or silicone. They should be as short as possible,
with an appropriate hose hanger. If the milk hose is crimped or allowed to loop, milk flows will be interrupted, which leads to irregular fluctuations in teat-end vacuum. The milk hose should attach to an inlet located in the top third of the milk pipeline, at the eleven or twelve o’clock position. Inlets should be self-draining, self-closing and should not cause milk flow restrictions that would result in irregular teat-end vacuum fluctuations.

The milk pipeline

The milk pipeline serves two important functions: transporting milk from the cow to the receiver jar and carrying air flow to provide milking vacuum to the teat end. Either glass or stainless steel can be used for milk pipeline construction. The milk line should form a complete circuit and must be rigidly supported from the floor in order to maintain the appropriate slope. It is generally recommended that milk lines be installed as low as is practical. In milking parlors, low pipelines are installed below udder level. In stall barns, high pipelines are used, but they should be no higher than 2 m above the cow platform. Milk moves by gravity through the pipeline to the receiver jar. The milk line must be self-draining and should have a continuous slope from the high point toward the milk receiver jar. The correct slope is important for the movement of milk and air during milking, as well as for proper cleaning of the system. In the construction of new tie-stall barns, it is recommended that the foundation, floor and gutter be sloped towards the milk house end. This will help to minimize pipeline height and to insure that line slope will facilitate drainage during milking and washing.

Line diameter is another important feature of milk pipeline design. In addition to line slope and the level of herd production, pipeline diameter will determine the number of milking units that a system can handle. Too many units will lead to milk line flooding and a reduction in air flow rate. Slugs of milk moving through the line is an obvious sign of milk line flooding. This problem will have a negative impact on milking time, herd production and udder health. The recommended minimum pipeline diameter is 51 mm (2 in.). At this pipeline size, high-producing herds should not use more than three milking units per pipeline slope. Thus, larger pipeline sizes are often recommended for new installations. Pipeline couplers or welds must prevent air leakage into the system.

Milk should flow into the receiver jar in a continuous, unimpeded fashion. When sufficient milk has accumulated, an electronic probe triggers the milk pump to transfer milk from the receiver jar to the bulk tank. A milk filter is inserted into the transfer system, as a mechanism to remove coarse impurities that may have entered the line. The receiver jar is connected to the main vacuum supply. A device called a sanitary trap is used to separate the ‘air only’ portion of the milking system from the ‘milk handling’ side of the system. The sanitary trap is designed to protect the vacuum supply from potential damage caused by the chemical cleaning and sanitizing solutions used to clean milk pipelines.

A milking system should have the capability of measuring the amount of milk from each cow. In older milking parlor systems, weight jars were often used for this purpose. They allowed for a quick visual means of monitoring individual cow production at each milking, as well as providing vacuum stability to the cow. However, they were expensive and represented a challenge to clean. More recently, milk metering systems have been developed that give an electronic digital readout of the milk volume produced at each parlor station. These systems can often be adopted to automatic data recording in an on-farm computer system. In stall barn pipeline installations, several types of mechanical milk meter are in use. It is important that any metering system not be restrictive to the flow of air and milk. These restrictions can cause a drop in teat-end vacuum and the occurrence of irregular teat-end vacuum fluctuations. Increased milking time, incomplete milk-out and new intramammary infections can result.

Bulk milk tank

The bulk milk tank is the vessel used to cool and store raw milk until it is picked up by the bulk milk transport truck. All tanks must be of an approved sanitary design and construction. They must be of sufficient capacity to cool and store up to 3 days of milk production. The cooling capabilities of bulk milk tanks are clearly specified. Appropriate cleaning and sanitizing procedures for bulk tanks are critical, in order to prevent bacterial growth and contamination of raw milk.

Relationship of milking equipment to udder health

The milking machine can influence new intramammary infection rates in several ways:

- The milking machine may be a carrier of mastitis pathogens from one cow to the next
- The milking machine may serve as a pathway of cross-infection within cows
- Malfunctioning or improperly used equipment may result in failure to relieve congestion in teat tissue. Eventually, teat end damage and intramammary infection can occur
- Abrupt loss of milking vacuum may create changes in air movement of sufficient force to move pathogens past the streak canal defenses. This phenomenon, known as the impact mechanism, was described earlier.

The pathogenesis of new infections related to machine milking probably involves all of these factors. However, even though the milking system becomes the focus of the herd udder health investigations, there is little evidence that machine factors are of primary importance in most problem herds. It has been difficult to link milking machine factors and prevalence of herd infection. Mastitis has been difficult to produce experimentally by altering machine function.

A great deal of research has been directed towards the identification of machine factors related to mastitis. Although many problems are identified, the only factors consistently associated with udder health problems are pulsation failure and the impact mechanism. Appropriate pulsation is important for sufficient teat end massage. Although continuous vacuum will remove milk from cows’ teats, eventually it will result in excessive congestion, edema and teat end damage. An adequate compressive load by the liner on the teat tissue is necessary to relieve the congestion. Mechanical failure of the pulsator, shortness of the liner barrel and a too-short liner rest phase are the most common examples of pulsation problems. The impact mechanism results from an abrupt loss of milking vacuum. Poor liner design has been shown to increase the frequency of liner slips. During a liner slip, a reverse pressure gradient occurs across the streak canal of the other three teats. Liner design has been shown to be very important in reducing the amount of slippage. In combination with liner slips, the vacuum fluctuations that result from pulsation problems can lead to new intramammary infection.

Even with the myriad of potential machine problems, milking equipment is not usually the major risk factor for poor udder health.

Maintenance and evaluation of milking equipment

The most important aspect of udder health management related to milking equipment is the establishment of an appropriate evaluation, maintenance and service schedule. Farm personnel should
incorporate an inspection of the equipment into their regular milking process. Many of the problems discussed in conjunction with the description of milking system components can be discovered during this daily inspection. In addition, the producer should have milking equipment serviced on a regular basis. Items such as the vacuum pump, regulator, pulsators and sanitary trap would be included in this check list. Also included in this inspection will be regular changing of the teat cup liners and other rubber parts. It is common for equipment dealers to schedule a regular visit to each farm client for the purpose of conducting this periodic maintenance schedule and for dispensing chemical cleaners and disinfectants used in the udder health management program.

A complete milking system analysis should be conducted on a regularly scheduled basis. This regular analysis is perhaps just as important as the initial design and installation of the system. Many dairy cattle specialists believe that a regular independent analysis will insure proper equipment function. Milking system analysis can be conducted by equipment dealers, government extension staff, veterinarians or independent technicians. All these individuals need the appropriate knowledge and training. It is essential to use some type of systematic milking system analysis worksheet to record various performance measurements and to identify components requiring service or upgrading. A complete system analysis should be conducted at least once a year, and records should be kept for future reference.

3. DRY COW MANAGEMENT AND THERAPY

The proper management of dry cows and late-gestation heifers is an important component of a mastitis control program. The dry period offers a valuable opportunity to improve udder health while cows are not lactating. However, the beginning and the end of the dry period represent periods of increased risk of infection. The objective of udder health management during the dry period is to minimize the number of infected quarters at calving. Two of the three major principles of udder health management must be met in order to achieve this objective. Infections present at the time of drying off should be eliminated and the rate of new intramammary infections during the dry period must be minimized. Thus dry cow therapy has a dual role in eliminating existing infections and preventing new infections during the dry period, and has been widely adopted by dairy farmers. If these two principles are followed, udders will be free of infection at calving and can be expected to produce a maximum amount of low-cell-count milk in the subsequent lactation. Intramammary administration of long-acting antimicrobial agents to all cows at drying off remains a routine recommendation.

Epidemiology of intramammary infection during the dry period

The development of effective udder health management strategies for the dry period requires an understanding of the epidemiology of intramammary infections in dry cows. This in turn requires an understanding of the incidence of new infections during the dry period and the types of pathogen involved. Risk factors that affect the susceptibility of dry cows should also be understood.

Incidence of new infections

The rate of new intramammary infections is significantly higher in the dry period than during lactation. The greatest increase in susceptibility is during the first 3 weeks of the dry period. In this period, the new infection rate is many times higher than during the preceding lactation as a whole. A second period of heightened susceptibility occurs just prior to parturition. The reported rates of new intramammary infection in the dry period vary widely. Reasons for these differences include the diagnostic criteria used and the types of organism considered to be major pathogens. There are also important herd-level effects, such as the prevalence of existing infections at drying off and the method of dry-off. The average rate of new infections in untreated dry cows is expected to be between 8% and 12% of quarters. Types of pathogen causing new infections during the dry period

Contagious pathogens are transmitted among cows and quarters in association with the milking process. Environmental pathogens are primarily contracted from contamination with organisms in manure and bedding. Teat skin opportunistic pathogens are present on the teat, particularly the teat end. Contagious, environmental and teat skin opportunistic pathogens need to be considered in designing mastitis control schemes for the dry period.

Exposure to environmental pathogens is likely to continue throughout the dry period; thus prevention of new dry period infection with environmental agents represents a considerably greater challenge. Herds that have implemented a basic mastitis control program still need to be aware of the importance of preventing environmental infections in the dry period. There are different rates of infection by the various environmental agents as the dry period progresses. For example, infections with environmental streptococcal species, Klebsiella spp. and Enterobacter spp. occur more frequently early in the dry period. On the other hand, E. coli infections tend to occur immediately before calving. Dry cow management strategies need to account for the risk of infection during the entire period from last milking until the next calving.

Risk factors that affect susceptibility in dry cows

Several factors contribute to the variation in susceptibility during the dry period. These factors include the following.

Teat end protection

The cessation of routine milking-time hygienic practices such as teat dipping allows bacterial subpopulations on teat skin to increase in number and diversity. S. aureus numbers are high immediately after drying off and environmental pathogens are more prevalent on teat skin late in the dry period and at calving time. Teat end lesions increase the likelihood of intramammary infections during the dry period. A plausible mechanism to explain this association is that teat end lesions increase the surface area available for bacterial colonization while presenting a variety of environmental niches. For instance, quarters with cracked teat ends were 1.7 times more likely to develop a new intramammary infection during the dry period than unaffected quarters. The streak canal of the teat is more penetrable by bacteria during the early dry period. The keratin plug in the streak canal must form early and completely in the early dry period in order to prevent penetration and growth of bacteria and decrease the incidence of new intramammary infections. However, this natural internal teat sealant does not form in some cows, and delay in formation is common. For instance, in cows in New Zealand, 45% of teats are open on day 7 of the dry period, and 25% are still open on day 35 of the dry period. Similar results were obtained in North American dairy cows. Quarters that remain open during the dry period are 1.8 times more likely to develop a new intramammary infection than quarters that have developed an effective keratin plug. Internal and external teat sealants are discussed further later in this chapter.

Swelling of the mammary gland, an increasing volume of secretion and leaking colostrum contribute to the high risk of new infection during the prepartum period.

Control of bovine mastitis
Resistance mechanisms within the mammary gland

Throughout the dry period there are marked changes in the composition of mammary gland secretions and in the concentration of protective factors such as leukocytes, immunoglobulins and lactoferrin. These changes probably influence the variation in susceptibility to both environmental and contagious pathogens. Substantial evidence exists that innate and acquired defense mechanisms are lowest from 3 weeks precalving to 3 weeks postcalving. This lowered responsiveness includes aspects of systemic and mammary gland immunity that may account, in part, for the increased incidence of peripartum disease. Polymorphonuclear neutrophil function is impaired during the peripartum period and may contribute to the increased incidence of mastitis following calving. Diminished lymphocyte responsiveness around calving has also been observed. The role of the cow in effectively transferring antibodies and cells to the mammary gland prior to parturition to insure high-quality colostrum is also an important function, and this may be affected by prepartum vaccination schedules and the ability of the animal to respond effectively.

Milk production at dry off

A high level of milk production at dry off increases the incidence of new intramammary infections at calving. It is reasonable to assume that high milk production at dry-off will produce a higher intramammary pressure, thereby increasing the likelihood of an open teat canal early in the dry period. High milk production at dry-off will also decrease the concentration of protective factors such as phagocytic cells, immunoglobulin and lactoferrin, thereby decreasing resistance within the mammary gland. The finding that cows leaking milk following dry-off are four times more likely to develop clinical mastitis in the dry period supports the concept that increased milk production at dry-off increases the rate of new intramammary infections.

Method of drying off

The industry standard method for cessation of lactation (drying off) is abrupt cessation of milking, whereby milking stops on the dry day scheduled for dry-off (all cows are usually scheduled to ‘go dry’ on the same day each week) in order to facilitate administration of dry cow intramammary antibiotics, vaccinations and vitamin E/selenium injections. Abrupt cessation is associated with a higher new intramammary infection rate in the dry period compared to intermittent cessation, although the increase in prevalence is most evident in cows that are not dry treated. The best approach to dry off cows may therefore be intermittent milking, although additional studies are required before the industry standard is altered. In particular, the method of drying off is probably less important with blanket dry cow therapy.

Parity

Older cows are more likely to develop new intramammary infections during the dry period. This increased predilection may be due to increased milk production at dry-off, increased prevalence of abnormal teat placement (increasing exposure of the teat end to pathogens) or increased prevalence of open teat canals because older cows have higher milk production.

Risk factors that affect susceptibility in heifers

An increased risk for intramammary infection in the preparturient period in heifers is associated with the presence of S. aureus or M. bovis in the herd, calving in summer, high herd bulk tank milk SCCs, poor fly control, mastitic milk fed to calves and contact with adult cows. Other risk factors are increased age at first calving, prepartum milk leakage, blood in milk and udder edema.

Udder health management strategies for dry cows

Antimicrobial therapy (dry cow therapy)

Antimicrobial therapy at the end of lactation (dry cow therapy) has been one of the key steps in mastitis control programs and has become the most effective and widely used control method for dry cows. The efficacy and advantages of antimicrobial therapy are well known. The use of effective dry cow products results in 70-98% elimination of existing infections. However, elimination of S. aureus is less successful. Dry cow therapy also reduces the incidence of new intramammary infections by approximately 80%. Long-acting antimicrobial preparations have been formulated to eliminate existing infections and to prevent new infections. These preparations include benzathine cephalin, benzathine cloxacillin and sustained-release formulations of erythromycin, nobilecbin and penicillin. The withholding period for milk from animals treated with these dry cow formulations ranges from 30-42 days after treatment. It is important that the label directions be followed carefully for the recommended dosage level, required withdrawal period, storage guidelines and expiry dates. A general recommendation is that dry cow treatment should never be administered within 1 month of the expected calving date. Single-dose syringe preparations of dry cow antibiotic treatment are recommended. The risk of contamination by environmental bacteria and yeast is much higher for multiple-dose bottles than single-dose syringes. If bulk containers are used, great attention should be paid to maintaining sterility.

The use of long-acting and short-acting antimicrobial intramammary infusions have been compared. In some cases, short-acting antimicrobial agents were more effective than long-acting ones in eliminating infections due to S. aureus or treating cows infected with major pathogens diagnosed twice before drying off. Intramammary infusion of cephalin sodium 15 days prepartum in heifers was effective in reducing intramammary infections during late gestation and reduced the occurrence of residues in milk during early lactation. The milk of heifers that calved less than 15 days after treatment may contain antimicrobial residues.

Intramammary infusion is a widely used and highly recommended procedure for mastitis therapy; however, there is a potential for the introduction of pathogens during the infusion process. Insanitary infusion practices can introduce antibiotic-resistant environmental organisms into the udder. Infection with opportunistic microorganisms, such as yeast or Nocardia spp., may cause more extensive udder damage than the original organism for which treatment was being administered. Adequate teat end preparation and careful dry cow treatment procedures can reduce this risk. Dry cow treatment procedures should be carried out as follows:

- Milk out the udder completely
- Immediately following teat cup removal, dip all teats in an effective teat dip
- Allow the teat dip to dry. If necessary, remove excess dip from teat ends with a clean single-service paper towel
- Disinfect each teat end by scrubbing for a few seconds with a separate alcohol-soaked cotton swab. Start with the teats on the far side of the udder and work to the near side
- Infuse each quarter with a single-dose syringe of a recommended dry cow treatment. Start with the teats on the near side of the udder. Use the partial insertion method of administration into the teat streak canal. Preferably, a modified infusion cannula should be provided with the treatment product
- Dip all teats in an effective teat dip immediately following treatment.

The necessity of using appropriate dry cow treatment procedures cannot be...
Nocardia spp. mastitis has been associated with blanket dry cow therapy, especially neomycin-containing products. However, Nocardia spp. were not found as a contaminant of the suspected products. Teat end preparation by scrubbing with an alcohol-soaked cotton swab was protective against the occurrence of Nocardia spp. infection when teats were experimentally contaminated with organisms immediately before drying off. Most commercial dry cow treatment products provide individually wrapped alcohol-soaked cotton swabs for use with each syringe. The use of good teat end preparation prior to intramammary infusion needs to be continually emphasized.

The method of intramammary infusion may be important. Partial insertion of the infusion cannula (up to 4 mm) results in fewer new intramammary infections and improved cure rates. The improvement with a short cannula is attributed to fewer organisms being delivered beyond the streak canal and decreased physical trauma to the streak canal. In addition, antiseptics are likely to be deposited within the streak canal should control local infections. Modified infusion cannulas for the convenient use of a partial insertion method of administration are now available for commercial dry cow products.

Another approach to preventing the problems associated with intramammary infusion would be the development of an effective systemically administered dry cow treatment. Preliminary results have indicated improved efficacy against S. aureus infections using a systemically administered quinolone antibiotic (norfloxacin nitocinate).

Blanket versus selective dry cow therapy
Three strategies for intramammary antimicrobial treatment of dry cows are available, although the current recommendation for all herds is blanket therapy:

- Blanket therapy (treat all quarters of all cows)
- Selective cow therapy (treat all quarters of any cow infected in one or more quarters)
- Selective quarter therapy (treat infected quarters only).

Although blanket dry cow therapy is a cornerstone of any mastitis control program, there is some controversy concerning the need to treat all quarters of all cows (blanket therapy) or only those quarters or cows requiring treatment. The controversy has gained momentum as the implementation of udder health management practices has reduced the prevalence of infection. The major reasons for selective therapy are:

- To avoid the elimination of minor pathogens, which may make cows more susceptible to environmental agents.
- To reduce the expense of treatment.
- To address increasing consumer concern regarding the routine administration of antibiotics to food-producing animals.
- To avoid the possible emergence of antibiotic-resistant organisms.

Each of these reasons should be carefully considered in making a decision between blanket and selective dry cow therapy. Selective dry cow therapy is preferable provided that an accurate, practical and inexpensive method for selecting infected cows is available. This is the major problem with selective dry cow therapy—in most herds the sensitivity and specificity of the test used for selection is not adequate.

As general udder health improves and bulk tank milk SCC remains low, producers question the need to continue dry treatment on all cows and are attracted by a potential reduction in costs for the purchase of dry cow treatment. However, selective therapy requires a decision as to which cows or quarters are to be treated. The sensitivity and specificity of currently available screening tests are inadequate as a basis for decisions concerning selective therapy. The history of the number of episodes of clinical mastitis, individual cow composite SCC during lactation and at dry off, CMT results during lactation or at dry-off and even bacteriological culture towards the end of lactation all result in leaving some infected cows untreated, but conversely result in the treatment of many uninfected cows. An important requirement for large-scale implementation of selective dry cow therapy is the development of a cheap, practical, sensitive and specific test to identify infected cows. The failure to prevent new intramammary infections during the dry period with the selective approach must also be considered. New infections in the dry period will become increasingly important as contagious pathogens are eliminated from herds. Finally, blanket dry cow therapy reduces new infection rates for quarters from approximately 14% to 7%. The increase in milk production alone resulting from prevention of these new infections provides enough return to offset the cost of treatment for all cows.

Information presently available indicates that the general recommendation should be for routine treatment of all quarters of all cows at the time of drying off (blanket dry cow therapy). There is a need to identify important management practices to limit new infections in untreated dry cows and to develop new screening tests to determine which cows should be treated. New environmental management methods and modern information processing capabilities may lead to the development of better selective dry cow treatment programs. These may include the administration of ancillary therapeutic agents. For instance, the intramammary infusion of recombinant bovine interleukin-2 along with cephalosporin sodium at drying off marginally increased the cure rate of intramammary infections associated with S. aureus, but not other pathogens, during the dry period compared with the administration of cephalosporin only. Interleukin did not affect the incidence of new intramammary infections for any pathogen group. However, the intramammary infusion of interleukin at drying off was associated with an increased incidence of abortion in dairy cows 3–7 days after the infusion.

Factors affecting the success of antimicrobial treatment of dry cows
Despite blanket dry cow therapy, some cows calve with infected quarters and some with clinical mastitis. Several risk factors affecting the results of dry cow treatment have been evaluated. Some of these factors are:

- **Number of quarters infected.** With S. aureus infections, there is a significant decrease in cure rate as the number of quarters infected per cow increases. Quarters from cows with either three or four of their quarters infected have a very poor cure rate.
- **Age of the cow.** As the age of the cow increases, the probability of S. aureus infections being cured by dry cow therapy decreases.
- **Somatic cell count before drying off.** The cure rate of S. aureus-infected quarters diminishes as the SCC prior to treatment increases. Controlling for age and number of quarters infected, there was a significantly lower cure rate in quarters with an SCC of more than 1 000 000 cells/mL.
- **Herd of origin.** There is a distinct herd effect on the success of dry cow therapy. The cure rate of S. aureus has been shown to be higher in herds with good hygiene and with a low prevalence of S. aureus infections at drying off.

There is considerable potential in using individual cow and herd-level information to predict the likelihood of a cure with dry cow therapy. For example, an older cow with three quarters infected with S. aureus and a persistently high SCC has a low probability of a cure.
development of information management systems to assist with therapy and culling decisions will clarify the expectations of dry cow treatment.

Persistent S. aureus infections represent only one of the shortcomings of antibiotic treatment for dry cows. Most dry cow products are formulated for efficacy against Gram-positive cocci. These antibiotics are of limited usefulness against Gram-negative bacteria. In other words, new coliform infections would not be prevented by this therapy. Even though dry cow products are formulated for sustained activity, the provision of adequate protection during the critical prepartum period is questionable. The persistence of effective levels of antimicrobial agents has been evaluated for various dry cow treatments, very few products have persistent activity until the time of calving.

Vaccination of the dry cow

Immunization and immunotherapy for the control and prevention of mastitis have been active areas of research. Effective vaccines would have to eliminate chronic intramammary infections, prevent new intramammary infections or decrease the incidence or severity of clinical mastitis. Currently available mastitis vaccines may reduce the incidence and severity of clinical mastitis but have not eliminated chronic intramammary infections or prevented new intramammary infections. The inability of vaccines to prevent infection may be due to the wide variety of pathogens, inadequate specific antibodies or the failure of antibodies to enter the mammary gland after infection. Currently available vaccines should be used as adjuncts to other more effective control strategies.

Vaccines have been developed to reduce the incidence and severity of clinical mastitis associated with Gram-negative pathogens. R-mutant bacteria have an exposed inner wall structure (core lipopolysaccharide antigens) that is highly uniform, even among diverse and distantly related Gram-negative bacteria. Vaccines containing killed R-mutant bacteria provide broad-spectrum immunity against a wide variety of unrelated Gram-negative bacteria. The most commonly used coliform mastitis vaccines are the R-mutant E. coli O111:B4, known as the JS vaccine, and the R-mutant Salmonella typhimurium, both of which are commercially available in the USA. R-mutant vaccines have been efficacious in the reduction of the incidence and severity of clinical mastitis due to Gram-negative bacteria. More than 50% of large (> 200 cows) dairy herds and more than 25% of all dairy herds in the USA are using core lipopolysaccharide antigen vaccines. No protection is provided against environmental streptococci and staphylococci, or the contagious pathogens. No effective vaccines are currently available for the control of mastitis due to S. aureus, S. agalactiae, environmental streptococci, and M. bovis.

The use of recombinant bovine cytokines as adjuvants to enhance specific immunity in the mammary gland of cows after primary immunization against indicate an enhancement of specific immunity in the mammary gland, which may be effective in mastitis immunization protocols.

Management of the environment for dry cows

Dry cows should be provided with an environment that is as clean and dry as possible. If this is not feasible in confinement housing, it is probably better to maintain dry cows on pasture. Variations in the load of coliforms and environmental streptococci in the environment are important predictors of new infection rates. Minimizing the exposure to environmental bacteria will reduce the new infection rate. However, some pasture conditions promote the crowding of cows under shade trees. In hot, humid and muddy conditions, heavy contamination of such a small area can result in a significant risk of new environmental infections in the dry period. In good weather, it is ideal to hold parturient cows in a clean, grassy area where they can be observed and assisted if necessary.

In confinement housing systems for dry cows, it is important to provide adequate space, ventilation, bedding and lighting to insure cleanliness and comfort. Maternity (calving) stalls should be bedded with clean straw, sawdust or shavings. Other important procedures for managing the environment for dry cows include adopting an effective fly control program. Clipping the hair on the udders, flanks and inside the hind legs will help reduce contamination. The words clean, dry, cold and comfortable summarize the ideal environment for dry cows. The words clean and dry also summarize the goal for the teat before attachment of the milking equipment.

Nutritional management of dry cows

A nutritionally balanced dry cow feeding program is important to insure udder health. A role has been suggested for specific nutritional factors in resistance to mastitis, especially over the dry period. Adequate levels of vitamin E and selenium in dry cow rations appear to be important for udder health at calving and in early lactation. This effect may be mediated through enhanced resistance mechanisms. Other vitamins and minerals may be important in udder health, but their role is less well substantiated.

Nutritional management of dry cows is also important for reducing the risk of milk fever, which is an important predisposing factor to mastitis in fresh cows. Appropriate body condition can be achieved by good nutritional management in late lactation. The association between body condition, energy metabolism and udder health needs further clarification.

Internal teat sealants

As discussed previously in risk factors for infection in the dry period, the keratin plug is a natural internal teat sealant that provides an effective barrier to new intramammary infections. High milk production at dry-off increases the likelihood that the streak canal remains open and presumably compromises formation of the keratin plug, thereby increasing the risk of intramammary infection.

A recent promising development in mastitis control has been exogenous internal teat sealants that are applied at dry off. The teat sealant product most extensively evaluated contains a heavy inorganic salt (bismuth subnitrate) in a paraffin wax base; this product does not have antibacterial properties but acts as a physical barrier to ascending intramammary infections. A New Zealand study involving 528 cows indicated that the internal teat sealant was retained for dry period lengths of more than 100 days, while producing a ten-fold decrease in the new intramammary infection rate, which was similar to that produced by dry cow intramammary infusion alone. In contrast, a UK study involving more than 1000 cows indicated that bismuth subnitrate teat sealant alone reduced the number of new intramammary infections to a great extent than intramammary dry cow infusion alone. The UK study had a greater incidence of new intramammary infections due to Gram-negative bacteria than the New Zealand study. A US study involving 437 cows found that an internal teat sealant at dry-off decreased new intramammary infections by 30% in the dry period and treated cows were 33% less likely to have a clinical mastitis episode between dry-off and the first 60 days of the subsequent lactation compared to untreated quarters. The addition of an antimicrobial agent is a logical addition to the bismuth subnitrate internal teat sealant and has been a routine addition to the teat sealant for some years in Ireland.

Bismuth subnitrate internal teat sealants clearly show promise for the prevention of new intramammary infections during the dry period. However, because bismuth subnitrate teat sealants do not eliminate...
existing intramammary infections, and an accurate method for determining the infection status of a quarter is unavailable (the exception being milk culture). The recommended application of internal teat sealants requires combined application with intramammary dry cow therapy. This combined therapy may be uneconomic. Widespread adoption of internal teat sealants will require an accurate test for determining intramammary infection status at dry-off. Finally, administration of internal teat sealants alone obviously requires proper aseptic technique.

External teat sealants

A longer-standing approach to providing a physical barrier to ascending infections is the use of external teat sealants, which were originally developed for use in lactating cows. The major problem with external teat sealants is the duration of adherence, which is too long for lactating cow use and too short for dry cows. Teat end lesions and teat length influence the adherence of external teat sealants.3

Widespread adoption of external teat sealants will require a product that provides prolonged protection but is easily removed at calving.

Teat disinfection

Postmilking teat disinfection is a very effective means of reducing new infections in lactating cows. However, the efficacy of teat disinfection in decreasing the incidence of new intramammary infections in the dry period has been discouraging. Daily teat dipping for the first week of the dry period is not effective in reducing S. uberis infections. The lack of efficacy of teat disinfection needs to be contrasted to the efficacy of internal teat sealants.

Intramammary devices

Intramammary devices have been developed for use in preventing new infections in both lactating and dry cows. However, there is conflicting evidence as to the reduction in infection rate in quarters fitted with these devices, and such devices are no longer being investigated. The incidence of clinical mastitis may be less in cows fitted with these devices compared to control cows but the prevalence of subclinical infection is unaffected.5 Intramammary devices induce a significant increase in postmilking SCC compared to control cows, and test-day SCCs may be higher than in control cows.

4. APPROPRIATE THERAPY OF MASTITIS DURING LACTATION

The early recognition and treatment of clinical cases remains an important part of a mastitis control program. Improvements in understanding of the epidemiology, pathophysiology, and response to therapy of various mastitis pathogens have clarified the role of intramammary and parenteral antimicrobial agents for the treatment of clinical and subclinical mastitis during lactation. This is covered extensively earlier in this chapter.

5. CULLING CHRONICALLY INFECTED COWS

The final step of the five-point mastitis control program is the selective removal of cows with chronic intramammary infection from the herd. Most producers have interpreted this recommendation to mean that cows with recurrent episodes of clinical mastitis should be eliminated. For example, some herds have established that cows having three or more clinical cases of mastitis in a lactation will be culled (the popular ‘three strikes and out’ approach). However, very little research has been conducted to determine the effect of various culling strategies on herd udder health status, and on the incidence of clinical cases.

Nevertheless, culling chronically infected cows meets one of the three guiding principles of mastitis control, namely the elimination of existing intramammary infections. Through the use of available monitoring techniques and the establishment of a defined culling program, a valuable opportunity exists to improve udder health by culling.

In general, a record of chronic mastitis and severe fibrosis detected on deep palpation should be the basis of a recommendation to cull. Culling is an effective and documented mastitis control measure for some specific mastitis pathogens. For example, the removal of infected cows is a key element of the recommended mastitis control program for herds with a high prevalence of S. aureus infection. Removal of cows found to be infected with S. aureus accounted for more than 80% of the costs involved in the control program. Culling is also important in the control of other mastitis pathogens that respond poorly to antimicrobial therapy. Herds with mastitis cases associated with M. bovis, Nocardioid spp., and P. aeruginosa should be aware of the benefits of culling infected cows.

A dairy herd culling program should be based upon consideration of the net present value of each cow in the herd as compared to the value of a replacement heifer. The net present value depends on the age of the cow, her potential for milk production, the stage of lactation and her pregnancy status. Factors that determine the likelihood of treatment success, such as pathogen and duration of mastitis, as well as the cost of treatment, also need to be considered in calculating the net present value of the cow with mastitis. After consideration of the relative importance of udder health in the overall herd health management program, additional economic pressure may be applied to cows with a specific udder health status. For example, if a S. aureus control program is a major priority in the health management program, additional economic pressure should be applied in removal decisions of cows with known S. aureus infections. As health management data collection and analysis improve in sophistication, decision analysis methods and expert computer models will be used to provide this information automatically.

Biosecurity for herd replacements

Replacement animals may be purchased to increase herd size or to maintain cow numbers following culling. Biosecurity measures must be used to insure that herd replacements are not infected with contagious mastitis pathogens (specifically S. aureus, S. agalactiae, M. bovis). However, an economic analysis of the different components of a biosecurity program has not been performed, and it is likely that some components of currently used programs are not cost-effective.

An optimal biosecurity program includes knowing the herd of origin, knowing the cows and protecting the home herd.

Know the farm of origin

- Request a bulk tank milk culture from the farm of origin
- Request the following data:
  - 6-12 months of bulk tank milk SCC; bulk tank milk bacterial counts
  - 6-12 months of records for clinical mastitis.

Know the cows

When purchasing single or small groups of animals the following pre-purchase procedures are recommended:

- SCC and clinical mastitis records for each cow to be purchased
- Results of bacteriological culturing of quarter milk samples from each cow on arrival (if lactating) or at calving (if late-gestation) for S. aureus, S. agalactiae and M. bovis. In general, the sensitivity of a single milk culture to detect the presence of intramammary infections due to S. agalactiae is approximately 95%, for S. aureus it ranges from 30-86%, and for M. bovis it is 24%
- A physical examination of each cow, including udder, milk quality and teat ends.

Protect the home herd

Consider all purchased animals as potential health risks to the home herd by doing the following:

- Maintain all newly purchased animals in separate or isolated facilities until
diagnostic tests for udder health have been completed and there is no evidence of infection that may spread to the rest of the herd (usually < 14 days quarantine).

- Evaluate all herd replacements for evidence of antimicrobial residues in milk.
- Milk all purchased animals last or with separate milking equipment until it is determined that they are free of infection.
- Obtain results of bacteriological culturing of bulk tank milk samples or string samples for S. aureus, S. agalactiae and M. bovis; culturing should be done on more than one occasion because the sensitivity of bulk tank milk culturing is not 100%, and is less than 50% for M. bovis.

6. MAINTENANCE OF AN APPROPRIATE ENVIRONMENT

The multifactorial nature of mastitis has been emphasized throughout this chapter. Intramammary infection results from a complex interaction between the cow, the mastitis pathogens and the environment. Thus, the control of unfavorable environmental influences is extremely important in dairy herd udder health management programs.

Intramammary infection involves exposure of the teat surface to potentially pathogenic microorganisms, entry of the pathogens into the gland via the teat duct and establishment of the pathogens in the mammary tissue, producing an inflammatory response. Many environmental factors can influence this process of exposure, bacterial entry and establishment of infection. For example, the type of bedding and manure management can have a great impact on the contamination of teat skin with microorganisms. Housing design can have an impact on the prevalence of teat injuries, which will influence intramammary invasion by mastitis pathogens. Extreme climatic conditions, poor nutritional management and cow stocking densities will influence the immune system and the establishment of intramammary infection. A comprehensive udder health management program should involve steps to minimize the detrimental influences of the environment.

Global environmental influences

Worldwide, there are major differences in dairy herd health and production systems. For example, the type of animal used, economics of production, climatic conditions, housing structures and management methods are widely variable. These differences greatly affect the interaction of cows with their environment, even though the predominant causative organisms are the same under different systems. Thus, there are major variations in the relative incidences of different pathogens, and in the importance of various approaches to mastitis control.

Classification of environmental influences

The influences of the total environment can be divided into:

- The external environment. All aspects of the environment outside the housing facilities make up the external environment. This includes the regional differences in climate, geography and agricultural tradition. There are also local factors within a region that can have an important influence. These local factors include the topographical features of the land, natural shelters from the climate and the availability of pasture.
- The internal environment. All environmental conditions inside the cow buildings make up the internal environment. The general internal environment includes the type of housing system, temperature, humidity and air quality. There are also specific internal environmental influences such as stall design, type of bedding, nutritional management and manure disposal. The milking environment has a major influence through the equipment, cow preparation methods and approach to general hygiene.

External environmental influences on mastitis control

There is minimal evidence that external environmental factors directly influence the incidence of mastitis; however, the external environment determines the way in which cows are housed, fed and milked. Through these associations, the external environment can be an important risk factor in problems with udder health in dairy herds.

Regional environment

The climate and geographical features of a region have implications for the prevalence of mastitis. The ambient temperatures and amount of rainfall often determine the types of housing and nutritional program used. Extremely hot or cold conditions interact with other predisposing management factors. In areas prone to severe rainstorms, teats may be exposed to wet or muddy conditions. The soil type, cropping policy and presence of other industries can also have an indirect impact on the prevalence of mastitis; for example, regions suitable for growing cereal grains will commonly use straw as a bedding material, which may favor the growth of environmental streptococcal organisms. In contrast, dairying areas close to the forestry industries may favor sawdust or shavings as bedding. The use of these materials may influence the incidence of coliform mastitis.

The socioeconomic structure and agricultural policy of a particular region can affect management factors known to influence udder health. These factors determine herd size and labor costs. Large herd sizes necessitated by economic conditions will dictate the housing, feeding and milking management practices employed. More recently, regional policy towards regulation of bulk tank milk SCC levels has had a profound impact on udder health status.64

Local environment

The local environmental factors such as the topography of the land, the presence of natural shelters and the type of pasture grown are thought to influence udder health status. However, direct scientific evidence is lacking. One important exception is ‘summer mastitis’, which affects nonlactating heifers and cows. This udder infection with A. pyogenes is greatly affected by the local environment, probably through the propagation of insects important in its transmission. Protected pastures increase insect populations and can result in a high incidence of infection.

Internal environmental influences on mastitis control

The incidence of new intramammary infections can be greatly affected by the management and facilities used in confinement dairying systems. General aspects of the internal environment exert their influence on all cows in the herd, such as the type of housing and milking system. Tie-stall barns pose different environmental stresses from a free-stall system. The air quality and noise levels can have an impact on animal health. The nutrient content of component feedstuffs can affect disease resistance.

Specific internal environmental factors exert their influence on an individual cow basis. For example, the stall design and typing system affect individual cows differently. Many epidemiological studies have revealed interactions between udder disease and internal environmental conditions. Most of these studies relate to European tie-stall and seasonal grazing systems. However, the results are generally relevant to most housing and management systems. Some of the most important general and specific influences of the internal environment are as follows.

Housing

Housing factors account for a great deal of the variation in udder health status between herds. In both tie-stall and free-stall barns, short and narrow stalls are...
associated with increased incidence of teat tramps and mastitis. An appropriate partition between stalls is beneficial. Stanchions or neckstraps with chains can restrict the movement of the cow and increase the risk of teat injury. This occurs especially as cows are rising. In addition, the use of electrical cowtainers has been associated with an increase in the rate of subclinical mastitis. The use of adequate amounts of a good bedding material will reduce mastitis incidence in both tie-stall and free-stall housing systems. Even though there are reports of specific bedding materials being associated with certain mastitis problems, the use of adequate amounts of properly maintained bedding is beneficial. Straw, shavings, sawdust, sand, shredded newspaper and other cushion systems have all been used effectively.

The climate and air quality maintained within a building can contribute to higher mastitis rates. Draughty conditions, high relative humidity and marked changes in indoor temperature over a 24-hour period can contribute to higher mastitis rates. Adaptation to adverse internal environmental conditions may cause stress, which can reduce the cow’s defense mechanisms. Indoor climate, especially temperature and humidity, can also account for differences in the concentration of pathogenic organisms to which cows are exposed.

Nutritional management
A complex relationship exists between the quantity and quality of feed and udder health status. Improper nutritional management can result in an increase in new intramammary infections, the exacerbation of pre-existing chronic infections, and an increase in clinical mastitis. Several mechanisms have been suggested for this association. An improper anion to cation balance in the dry cow ration is a predisposing factor for periparturient hypocalcemia, which, in turn, increases the risk of new intramammary infections. Feeding programs that result in excessively fat or abnormally thin cows may affect resistance to disease. Also, there is some evidence that feeds high in estrogenic substances may be detrimental to udder health.

The dietary concentration of some vitamins and minerals may have an important relationship to udder health. Studies have shown that intramammary infection is related to plasma concentrations of vitamin E and blood concentrations of selenium. Dietary supplementation of vitamin E and selenium improved the natural resistance of the mammary gland to infection. Associations between udder health and the levels of vitamin A, beta-carotene, zinc and other nutrients have been proposed but are not well documented.

Management approach
Cow supervision, decision-making and general animal care by dairy herd managers may play important epidemiological factors in the relationship between environment and udder health. For example, lack of consistency in the performance and timing of various herd activities results in decreased udder health status. Irregular intervals between milkings should be avoided.

General hygiene
Even outside the milking environment, general hygiene can greatly influence the exposure of the udder and teats to pathogenic bacteria. The degree of hygiene achieved is directly related to the type of housing, the amount of bedding and the efficiency of manure removal. Worldwide trends towards increasing herd sizes and decreasing labor force necessitate more emphasis on the importance of cow hygiene.

Use of recombinant bovine somatotropin
It has been suggested that the use of bovine somatotropin may increase the incidence of clinical mastitis by an indirect mechanism that acts through increased milk production. Controlled field studies have shown that the use of bovine somatotropin is not associated with an increase in the incidence of clinical mastitis, milk discarded because of therapy for clinical mastitis, or culling for mastitis.

Environmental control in an udder health management program
There is a strong association between herd udder health status and the number and severity of environmental stressors. Veterinarians responsible for udder health management programs should have a good understanding of the importance of environmental management. The three major objectives of environmental control for improvement of udder health are:

- To prevent contamination of the teat end
- To prevent invasion of mastitis pathogens
- To prevent pathogens from establishing in the mammary gland

The important steps in achieving these three objectives have been discussed. For example, an adequate housing system and manure handling are important to limit bacterial contamination of the teats. The prevention of environmentally induced teat injuries will aid in preventing invasion of pathogens into the gland. The producer’s approach to cow management, control of the nutritional program and insuring that the internal environment is appropriate, will all greatly improve host defense mechanisms and prevent intramammary pathogens from establishing within the gland.

7. GOOD RECORD KEEPING
Good record keeping involves the collection of useful data to monitor performance, calculation of appropriate indices and decision-making based on comparison to target levels. For acceptable performance the monitoring process is repeated and the cycle continues. If performance is not acceptable, further evaluation and analysis is carried out and a plan of action is instituted. Once again, the monitoring process carries on and the cycle continues. For many of the health management programs in food animal practice, a limiting factor is the availability of accurate and objective data. With respect to udder health, data have been readily available. Bulk tank milk SCC, individual cow composite SCC and bacteriological culture results are all accessible and useful. These data provide the information necessary to monitor udder health status and to make specific health management decisions. However, problems can still exist. Herds with a low prevalence of infection and very low bulk tank milk SCC can still have a high incidence of environmental infections and clinical mastitis cases. Thus, an important step in an effective udder health management program is the maintenance and use of mastitis records. The increasing adoption of computerized dairy health management record systems provides an opportunity to make effective use of clinical mastitis episode and therapy data. Even without a computerized system, manual records for clinical mastitis are easy to implement and use.

Objectives and uses of clinical mastitis records
The objective of maintaining computerized or manually recorded clinical mastitis episode records is to complete the decision-making capabilities of a mastitis control program. The availability of this information will allow completion of the health management cycle over the entire spectrum of herd udder health situations.

There are several important uses of clinical mastitis records:
- To assess the risk factors associated with clinical mastitis episodes
- To institute the necessary changes to the udder health management program
- To improve overall herd health status
- To evaluate the success of herd health management practices
- To provide data for the development of herd health management programs
- To increase the profitability of the dairy operation
To evaluate lactational and dry cow therapy programs

To provide information useful in the evaluation of net present value of individual cows for the purposes of culling decisions. Without the ready availability of accurate data surrounding mastitis events, decisions associated with therapy, culling and the removal of risk factors are difficult to make.

Recording clinical mastitis data

There is a limited amount of specific data necessary to make effective use of mastitis records as a health management tool. The cow identification, date of the clinical episode occurrence, type of therapy used and the date that milk withholding will be complete are the essential pieces of information. If a manual record system is used, it will be important to add the lactation number, the date of calving and the most recent test date production. A standard form that calculates the distribution of clinical episodes by lactation number and by stage of lactation is desirable. These are the same distributions often provided with an individual cow SCC report. A record form that allows the recording of treatment used, the number of days treated, milk withholding periods and an estimate of the costs associated with clinical mastitis has been described.63,64

Using clinical mastitis monitoring systems

Since clinical mastitis is a common event in dairy production, it is ironic that these records have not traditionally been kept. The key to overcoming this hurdle is the regular use of this information for health management decisions. Some of these uses and decisions are as follows.

Cow versus herd clinical mastitis problems

Calculation of the percentage of cows affected in the herd and the average number of clinical episodes per affected cow will aid in determining if the clinical mastitis is more of an individual cow problem or a herd-level issue.65

Probability of recurrence of clinical mastitis in the same lactation

The number of animals with repeat cases of mastitis divided by the total number of clinical cases gives an estimate of the likelihood of recurrence. The same calculation can be made for specific parity groups. This information can be useful to characterize the problem, and for culling decisions.

Stage of lactation and seasonal profile

If clinical mastitis data is collected consistently over a considerable period of time, potentially useful problem-solving information can be derived. For example, calculating days in lactation at first occurrence can help to identify specific risk factors for new intramammary infections. There is a higher proportion of clinical occurrences during the first few weeks after calving. However, analysis of clinical mastitis records might yield a different stage-of-lactation profile. In these cases, the evaluation of potential nutritional, environmental or other stress factors would be indicated. There may be different immediate and long-term solutions that should be implemented.

Analysis of clinical mastitis records over several years may identify a significant seasonal pattern, such as the documented seasonal pattern for bulk tank milk SCC data and antibiotic residue violations. Action may be necessary to deal with seasonal environment and housing problems that impact upon new infection rates.

Days of discarded milk

It is very common for producers to have an aggressive attitude towards the treatment of clinical mastitis. This approach may result in huge economic losses if waste milk is not fed to calves. These losses are largely the result of discarded milk during the clearance of antibiotic residues from treated cows. Calculating the days of discarded milk may suggest that the mastitis therapy program during lactation should be evaluated. Establishment of an appropriate treatment program and careful selection of cows for therapy might significantly decrease the need for discarded milk. In addition, cows that are responsible for a large percentage of the discarded milk should be identified for selective removal. The calculations from mastitis records that can help to clarify these issues include:

- Total days of discarded milk for the herd
- Days of discarded milk per episode
- Days of discarded milk by lactation number
- Accrued days of discarded milk for individual cows

8. MONITORING UDDER HEALTH STATUS

An important step missing from early mastitis control programs was the monitoring of udder health status. Although intuitively it appears necessary to chart the progress of any program, it is only quite recently that monitoring has been included as an integral component of udder health management. Monitoring is now recognized as the third key principle of mastitis control. The development of objective, inexpensive and efficient methods of monitoring udder health has made it much easier to complete the health management cycle for this component of herd programs.

The implementation of SCC measurement on bulk tank milk and on individual cow samples has been widespread throughout the major dairy regions of the world. Since SCC is objective and standardized, it can be used to evaluate the progress of regional control programs. This has allowed rapid improvement in udder health compared to the other components of dairy health management programs. Regional authorities have established new regulatory limits and targets for milk quality performance.

Implementing an effective system of monitoring udder health involves:

- Monitoring udder health at the herd level
- Monitoring udder health of individual cows
- Use of cowside diagnostic tests

This discussion will emphasize the use of monitoring methods for decision-making and problem-solving in udder health management programs. Monitoring of udder health should be done at the herd level and individual cow level.

Monitoring udder health at the herd level

The monitoring of bulk tank milk provides the best method to evaluate the overall udder health status of dairy herds and the effectiveness of mastitis control programs. Herd-level monitors of udder health include bulk tank milk SCC, bulk tank milk bacteriological culture and herd summaries of individual cow SCC data. Analysis of clinical mastitis records is also useful for monitoring udder health at the herd level.

Bulk tank milk somatic cell counts

Most milk marketing organizations and regional authorities regularly measure SCC on bulk tank milk as a monitor of the milk quality and udder health status of each herd. Many of these agencies use bulk tank milk SCC for penalty deductions or incentive payments. Improvement in bulk tank milk SCC is associated with improvement in other measures of milk quality such as bacterial counts, inhibitor test violations and milk freezing point.66 Countries and regions set milk quality targets using this SCC data, with milk being rejected from processing plants when the bulk tank milk SCC exceeds 400 000–1 000 000 cells/mL, depending on the country.

Several management practices are associated with low, medium and high SCC in bulk tank milk.67 Postmilking teat disinfection and dry cow therapy are most
frequently associated with herds with a low bulk tank milk SCC. In herds with a low bulk milk SCC, more attention is given to hygiene than in herds with a medium or high bulk tank milk SCC. Cubicles, drinking buckets and cows are cleaner in herds with a low bulk tank milk SCC. Cleaner calving pens and cubicles for herds with low bulk tank milk SCC coincide with the observations that bedding for lactating cows and in maternity pens is drier for herds with a low bulk tank milk SCC. In herds with a high bulk tank milk SCC, a higher percentage of cows are culled because of a high SCC.

The incidence of clinical mastitis in dairy herds may not be different among those with low, medium and high bulk tank milk SCC. However, clinical mastitis associated with Gram-negative pathogens such as E. coli, Klebsiella spp., or Pseudomonas spp. occurs more commonly in herds with a low bulk tank milk SCC. Clinical mastitis associated with S. aureus, S. dysgalactiae, and S. agalactiae occurs more often in herds with a high bulk tank milk SCC. Systemic signs of illness associated with clinical mastitis occur more often in herds with a low bulk tank milk SCC. In herds with a high bulk tank milk SCC, cows with a high milk SCC were culled. In herds with a low bulk tank milk SCC, more cows were culled for teat lesions, milkability, udder shape, fertility and character than in herds with a high bulk tank milk SCC. In herds with a low bulk tank milk SCC, cows were culled more for export and production reasons.

Herd average of weighted individual cow somatic cell count

The arithmetic mean of individual cow SCC values, weighted by the cow's milk production, is also a good measure of the general udder health status of the herd. It should be noted that the high degree of variability of SCC measurements makes it inappropriate to compare this means directly with the bulk tank milk SCC.

Other herd-level somatic cell count monitors

There are several other calculations using individual cow SCC data that are useful for monitoring herd udder health. In general, these indices attempt to use mathematical calculations to reduce the impact of individual cows and to measure the change over time. These summaries are used to assist producers in the use of individual cow SCC information at the herd level. These indices include the following.

Herd average somatic cell count linear score

The use of linear score can simplify SCC interpretation and buffer the effects of individual cows with very high values. Thus, the herd average of SCC linear score is a very useful monitor of herd udder health status. A realistic goal for most dairy herds is an average linear score of less than 3.0, equivalent to fewer than 100 000 cells/mL. It is not correct to estimate herd production loss from the average linear score using individual cow linear score–production loss relationship developed for bulk tank milk SCC.69

Percentage of herd over somatic cell count threshold

Interpretation of SCC and linear score requires the choice of a threshold value for classification of cows as positive and negative. The threshold value used ranges from 200 000–400 000 cells/mL. A useful herd goal for subclinical mastitis is to have less than 15% of cows with SCC values greater than 200 000–250 000 cells/mL (prevalence). A second goal is to have fewer than 5% of cows developing new subclinical infections each month (incidence).

Percentage of herd changing somatic cell count to over threshold

Most uses of SCC data focus upon the determination of current udder health status. In other words, SCC is used as an estimate of the prevalence of existing infections in the herd; however, an important objective of a mastitis control program is to minimize the number of new intramammary infections. The change in the SCC of individual cows from month to month can be used as an estimate of the rate of new infections, and the use of SCC data in this way has been evaluated.80 Using SCC changes from month to month as a test for the rate of new infections has low sensitivity and high specificity. More research is needed on the usefulness of SCC to monitor the occurrence of new infections.

A popular way to represent these data graphically is to plot the SCC value (or linear score) for the current month on the y axis and the SCC value (or linear score) for the preceding month on the x axis. This graphing arrangement is preferred because the current SCC value is dependent, in part, on the previous SCC value. Using this graphical approach, individual SCC values in the upper left quadrant are new infections, values in the upper right quadrant are persistent infections and values in the lower right quadrant are resolved infections.

Bacteriological culture of bulk milk

Although SCC is widely used for monitoring udder health status in dairy herds, decision-making often requires information about the prevalence of specific pathogens. With the regular collection of bulk tank milk samples for the purposes of quality monitoring programs, culturing of bulk tank milk is an attractive alternative to culturing milk from individual cows. Bulk tank milk culture has been formally evaluated as a mastitis screening test.71 For the major mastitis pathogens, bulk milk culture had a low sensitivity. Even in herds infected with S. agalactiae, repeated bulk milk cultures were necessary to detect positive herds. Mastitis pathogens of greatest interest are contagious pathogens, such as S. agalactiae, S. aureus, M. bovis, and C. bovis.

The standard plate count (plate loop count) provides an estimate of the total numbers of aerobic bacteria in bulk tank milk and is an important measure of milk quality and udder health. It is most commonly used to evaluate the efficiency of cleaning the milking system. A standard plate count of less than 10 000 cfu/mL can be achieved on most farms and less than 5000 cfu/mL should be the goal. Standard plate counts higher than 10 000 cfu/mL indicate milking of cows with dirty teats or mastitis, poorly sanitized milking equipment or delayed cooling of milk in the bulk tank. Many herds routinely have bacteria counts of 1000 cfu/mL or less. Total bacterial counts have some value as an early warning system because up to 50% of violations of the standard are associated with mastitis-related bacteria. For example, bacterial counts in the milk of acute clinical cases may be as high as 10 000 000 cfu/mL. Milk from subclinically infected quarters may contain 1000–10 000 cfu/mL, and normal quarters yield less than 1000 cfu/mL. In nonmastitic cows, higher counts, up to six times higher, are seen in housed cows than in pastured cows.

The preliminary incubation count is an estimate of the total number of cold-living bacteria. As such, the preliminary incubation count provides an index of milk production on the farm. A preliminary incubation count below 50 000 cfu/mL can be achieved on most farms, with less than 10 000 cfu/mL being the goal. The preliminary incubation count should be less than 3–6 × the standard plate count.

Herd-level measures of clinical mastitis

The incidence of clinical mastitis, calculated as cases per 100 cows per year, can provide a rough assessment of new intramammary infections.72 The goal is less than two new cases per 100 cows each month (equivalent to < 24% of cows affected each year). Calculation of the total treatment days can provide a herd-level assessment of the approach to therapy of clinical mastitis, as well as an estimate of the economic losses.
In a random sample of dairy herds in the Netherlands, the following risk factors were associated with a higher incidence of clinical mastitis: one or more cows leaking milk, one or more cows with trampled teats, no disinfection of the teats after calving, consistent use of postmilking teat disinfection, Red and White cattle as the predominant breed, and an annual bulk tank milk SCC of less than 150,000 cells/mL. Factors associated with a higher rate of clinical mastitis caused by E. coli included cows with trampled teats, no disinfection of the maternity area after calving, consistent use of postmilking teat disinfection, use of a thick layer of bedding in the stall and the stripping of foremilk before cluster attachment. Factors associated with a higher rate of clinical mastitis caused by S. aureus included Red and White cattle as the predominant breed, cows with trampled teats, stripping of foremilk before cluster attachment, no regular disinfection of the stall, no regular replacement of stall bedding and an annual bulk tank milk SCC of less than 150,000 cells/mL. Teat disinfection appeared to increase the incidence of clinical mastitis associated with E. coli, which may be explained by the higher incidence around calving and during early lactation, when the resistance of cows is low combined with an increase in the numbers of environmental bacteria associated with maternity pens.

Monitoring udder health of individual cows

Earlier in this chapter, one direct (culture) and several indirect tests for intramammary infection were described. Currently, four methods are widely used to detect subclinical mastitis: culture of composite or quarter samples, SCC values of composite or quarter samples, and CMT and electrical conductivity of quarter samples. Currently, cow level data (culture or SCC) are the most commonly used of these four monitoring tools, but the usefulness of these tests varies depending upon their cost, sensitivity, specificity, convenience and availability.

Bacteriological culture of milk

Culture of aseptically collected milk samples has been a cornerstone of mastitis control programs. Extensive diagnostic laboratory systems have been developed for the culture of milk. For many years, milk bacteriology has been recognized as the gold standard of mastitis diagnostic tests. The sensitivity and specificity of milk bacteriology are now being examined and, as the costs of laboratory procedures have risen, there is an increasing need to justify diagnostic expenses. However, there is still an important need for information concerning the predominant types of mastitis organism active in a herd.

Several schemes have been proposed for obtaining a pathogen profile of the mastitis pathogens in a herd. The following suggestions are offered as the most appropriate times to collect samples for milk bacteriology:

- Pretreatment milk samples from clinical cases. Samples should be frozen, collected at a herd visit, and submitted for culture.
- Cows that have an increased SCC. At each scheduled herd visit, each cow that has increased in SCC over a preset threshold is sampled and the sample is submitted for culture.
- A composite milk sample from each lactating cow in the herd. This whole-herd culture would be conducted annually or more frequently depending upon the herd situation. This method is most appropriate for herds having problems with contagious pathogens, but the economics of this approach have not been determined.
- Culture of cows at a specific management event, for example milk culture at drying off and at the first milking after calving, can be useful for assessment of the dry cow management program.

The cost-effectiveness of any one or a combination of these methods of obtaining a bacteriological profile of a herd's milk will depend on the current situation in the herd. For the vast majority of dairy herds, the routine culture of cows for subclinical mastitis diagnosis is not cost-effective. In fact, herds with a low bulk tank milk SCC and a low incidence of clinical mastitis episodes can conduct an efficient udder health management program without culturing milk. It is very wise, however, to collect pretreatment milk samples from clinical mastitis cases. These samples can be frozen without significant alterations of the culture results for most pathogens. The samples are collected at a scheduled herd visit and submitted to the laboratory. In most herds, this approach will give a meaningful bacteriological profile of the herd and assist in assessment of the treatment protocol.

C. bovis is not a common cause of clinical mastitis on most farms but is frequently found in random milk samples. Because C. bovis is highly infectious and susceptible to teat disinfection, it has been suggested that C. bovis prevalence could be used as an indicator of teat-dipping efficiency in a herd, either of the intensity of the dipping or of the efficacy of the dip. The fact that C. bovis is limited in its colonization to the streak canal makes it valuable as a monitor of teat disinfection.

Somatic cell counts

Several management decisions can be based on individual cow composite SCC. Before any decisions can be made using SCC, criteria must be established to categorize cows based on their SCC results. This involves establishing threshold values or other criteria. The recommended threshold is 250,000 cells/mL in herds with a low prevalence (<5%) of subclinical mastitis, providing a sensitivity of 0.55 and specificity of 0.96. In comparison, the recommended threshold is 200,000 cells/mL in herds with a high prevalence (40%) of subclinical mastitis, providing an apparent sensitivity of 0.73-0.89 and a specificity of 0.86. A clinically more appropriate approach is to calculate likelihood ratios using test sensitivity and specificity, estimated herd prevalence and a spreadsheet. Cows are identified for further investigation based on their SCC, using three different methods:

- Change in SCC to over the threshold. A cow with a marked increase in SCC from one month to the next would be identified as potentially being infected.
- Persistently elevated SCC. Cows with a persistently elevated SCC month after month would be identified for management intervention. The lactation average linear score and the lifetime linear score are also useful in this respect. This information is especially useful if dry period therapy has already been unsuccessful for the cow in question.
- Percentage contribution to herd average. An estimate of the percentage of the SCC in bulk tank milk contributed by each problem cow can be calculated using individual cow test-day milk weights and SCC data. It should be noted that cows with high milk production and intermediate SCC levels may make a significantly higher contribution to SCC than some cows with a very high SCC but low production. It is not uncommon for a few problem cows to be responsible for more than 50% of the cells in the bulk tank, particularly in small herds. In most circumstances, the cows with the highest percentage contribution merit immediate action.

With these methods of identifying individual cows based on SCC results, several udder health management decisions can be made, including:

Selection of cows for milk bacteriological culture

The importance of having a good bacteriological profile of the
Control of Bovine Mastitis

1. **Introduction**

   Bovine mastitis is a common disease affecting dairy cows, characterized by inflammation of the mammary gland. It can significantly reduce milk production and quality, leading to economic losses for dairy farmers. The distribution of mastitis incidents is often segmented into stages of lactation, with distinct patterns observed in dry cows, early lactation, and later lactation periods.

2. **Problem-posing using individual cow see data**

   Individual cow see data can be used to assess mastitis risk, where a marked increase in see (suppurative mastitis) or a steady increase over time (chronic mastitis) indicates potential problems. See values above 12 or average see above 10 are often associated with an elevated risk of mastitis.

3. **Criteria for selecting cows for dry cow treatment**

   Selection of cows for dry cow treatment should be based on a combination of factors, including previous history of mastitis, stage of lactation, and production level. High-risk cows may include those that have had mastitis in the recent past, or those that are expected to have a high production level in the upcoming lactation.

4. **Problems with selective dry cow therapy**

   A blanket dry cow therapy is not always cost-effective, as herd-specific mastitis patterns are often observed. Selective therapy, based on previous history and risk assessment, can be more effective.

5. **Utilizing management procedures to limit intramammary infections**

   Management procedures to limit intramammary infections include disinfection of milking equipment, segregation programs, and regular monitoring of herd health. These practices are crucial in preventing the spread of mastitis and maintaining herd productivity.

6. **Conclusion**

   In conclusion, a comprehensive approach to dairy farming that integrates management practices, monitoring, and treatment strategies can significantly reduce the incidence of mastitis and associated economic losses. Regular review of herd health data and adaptation of management strategies based on these insights are key to effective mastitis control.

---

*Note: The above content is a simplified representation of a comprehensive approach to the control of bovine mastitis, focusing on key aspects such as the importance of see data, criteria for treatment, and management strategies.*
for some risk factors for new infections. A mastitis problem due to environmental pathogens in a free-stall operation can be difficult to solve. Calculating the percentage of cows with a SCC greater than 250,000 cells/mL for each milking group can help to determine where the problem is most severe. If a specific milking order is followed, as is the case in most tie-stall systems, the distribution of cows with elevated counts according to milking order can demonstrate weaknesses in milking hygiene.

What is the problem and why has it occurred? The information obtained by answering the questions who, when and where in the problem-solving process can go a long way toward defining what the problem is. Prevalence distributions can be combined with the incidence of clinical mastitis, information from milk cultures and an estimate of the financial losses, in order to complete the picture. Subsequently, specific solutions will be aimed at why this problem might exist.

With the development of computerized dairy health management records systems, the epidemiological analysis of udder health information can be greatly simplified. Ultimately, specific risk factors would be automatically tested for statistical significance. In addition, the relative importance of many potential risk factors would be evaluated.

9. PERIODIC REVIEW OF THE UDDER HEALTH MANAGEMENT PROGRAM

Many aspects of mastitis control, such as milking management and therapy of clinical cases, become routine practices. However, changes continue to occur in the udder health status of the herd, environmental conditions and available technology. With these changes, the current udder health management program may no longer be appropriate. New employees may be introduced and it is possible that various steps are not being appropriately implemented. In some dairy herds, management practices are passed on from previous generations without critical examination. Mastitis results from a continually evolving relationship between microorganisms, the cow and the environment. Any program intended to limit problems from these relationships needs to be re-evaluated on a regular basis.

An effective udder health management program should undergo regular periodic review. This process of appraisal should involve the producer and the herd veterinarian, although input may be sought from various farm management advisors. The review should be objective and thorough, but simple and easy to conduct. The use of a standard investigation form structured on the 10 steps of the mastitis control program is recommended. The same standard form can be used for the investigation of problem herds.

10. SETTING GOALS FOR UDDER HEALTH STATUS

The establishment of realistic targets of performance for various udder health parameters is the final component in an udder health management program. These goals are important to determine whether there have been shortfalls in the milk quality and udder health performance. The goals should be realistic and achievable, as well as having economic significance. In addition, the targets must be easily measured and should be accepted by all members of the farm management and labor team.

The setting of appropriate goals for mastitis control efforts is crucial for completion of the health management cycle. In some cases, the target will be the industry reference value, however in most situations it will be a farm-specific level of performance.

Relationship of udder health to productivity and profitability

Mastitis is generally considered to be the most costly disease facing the dairy industry. The reduced profitability is due to two major factors:

- Reduced milk production associated with subclinical mastitis accounts for approximately 70% of the economic loss
- The treatment costs, culling and reduced productivity associated with clinical mastitis are responsible for the remaining losses.

Production losses from increased somatic cell count

It is well accepted that milk production decreases as SCC increases, but the relationship between SCC and milk production is curvilinear for individual cattle but approximates a straight line when a logarithmic transformation (such as linear score) is used. Estimates of the milk production losses range from 3–6% with each one unit increase of linear score above 3. The loss in first-lactation heifers is greater than that in older cows. A general rule of thumb would suggest that there is 5% loss for each unit of linear score increase above a linear score of 3.

There is also a relationship between bulk tank milk SCC and milk production in that a linear decrease in herd milk production with an increase in bulk tank milk SCC. Estimates of the production loss range from 1.5–3.0% for each increase of 100,000 cells/mL over a baseline of 150,000 cells/mL. Using an average of these estimates, daily milk and dollar losses can be calculated from bulk tank milk SCC and herd production levels.

Clinical mastitis and lost productivity

Economic losses associated with the treatment of clinical mastitis arise from the cost of drugs, veterinary services and milk discarded. In addition, decreased milk production, premature culling and replacement heifer costs are also significant. However, more than 80% of the loss attributed to a clinical episode involves the discarding of nonsaleable milk and decreased milk production.

ASSESSMENT OF THE COST-EFFECTIVENESS OF MASTITIS CONTROL

Dairy producers look to their veterinarian for information and services related to mastitis and its control. With this motivation, veterinarians should be able to implement comprehensive udder health management programs on the majority of dairy farms. In order to achieve a high rate of implementation of mastitis control strategies, it may be necessary to demonstrate the cost-benefit ratio of the suggested practices before they are adopted. A reassessment of their impact over time may also be useful.

Mastitis control is feasible, practical, and cost-effective. The economics of the efforts of a mastitis control program in a herd can be estimated. There are several steps necessary to complete this assessment:

1. Programs for monitoring udder health and for establishing achievable goals must be in place for an economic assessment.
2. The losses resulting from mastitis must be quantified. The amount of reduced milk production resulting from increased SCC is calculated. In addition, costs associated with the discarded milk and treatment of clinical cases must be estimated.
3. The udder health management program to be implemented must be described. An accounting system should be established to calculate the costs associated with this program.
4. Using an estimate of the potential loss for a hypothetical herd with no mastitis control efforts, the profitability of the herd’s current udder health management program is determined.
5. By estimating the costs of implementing new udder health...
This economic assessment is done using a computer spreadsheet program. With such a computer program, veterinarians can simply and rapidly input actual values for a particular farm, and assess the economic circumstances. The impact of each element of control can be considered from the point of view of a cost–benefit ratio. The results of economic assessment will vary widely from farm to farm, but usually the following conclusions are made:

- Mastitis will remain a costly disease, even with implementation of properly applied, effective control programs.
- Loss of milk production attributable to subclinical infection will remain a major cause of economic loss due to mastitis in most herds.
- Proper application of simple, inexpensive mastitis control procedures will have a significant impact on profitability, and will bring higher returns on investment.

**REFERENCES**

suckling lambs. Ulcerative dermatosis of the teats in lactating ewes has lesions similar to those of herpes mammillitis in cows. It is a disease of housed ewes and may be initiated by bedding on infected straw. Mastitis and teat deformity are common sequels. The etiology varies from Staphylococcus aureus to coagulase-negative staphylococci or Pasteurella spp.\(^1\)

**LESIONS OF THE BOVINE TEAT**

Traumatic injuries to teats are very common and range from superficial lacerations to deep lacerations into the teat cistern with the release of milk through the wound. Accidental trampling of a teat by a cow may cause amputation of the teat.

Chapping and cracking of the skin of the teats is common in dairy and beef cattle. The cracks in the skin are often linear and multiple and are painful when palpated or when the milking machine teat cups are applied to the affected teats. Cracks of the skin of the teats initiated by milking machine action can be aggravated by environmental factors to create chapping of the teats. The condition is common when adverse weather conditions follow turn-out in spring. Linear lesions appear on the teat wall near the teat–udder junction and extend transversely around the teat. The addition of 10% glycerin to the teat dip provides an excellent method of improving teat skin condition.

Frostbite of teats occurs in dairy cows housed outdoors during severely cold weather without adequate bedding. The skin of the teats is cold, necrotic and oozes serum. Usually the front teats are more severely affected than the rear teats because the latter are less exposed to adverse ambient temperatures.

Teat end lesions are common in dairy cattle.\(^3\) Lesions include teat canal erosion, teat canal prolapse, prolapse of the meatus, erosion of the meatus and teat orifice erosion. Limited information is presently available as to the mechanism of development for these lesions and their clinical significance; one study found no association between the presence or absence of a teat end lesion and intramammary infection.\(^3\)

It is normal to see a 2 mm wide white ring around each teat orifice of machine milked cows. The first stage of a teat orifice abnormality occurs when this ring undergoes hypertrophy, keratinization, and radial cracking. Progression leads to increased hypertrophy, secondary bacterial infection, scab formation, erosion of the distal teat canal and eventually teat orifice erosion. Improper milking machine function can produce teat orifice abnor-

malities. Excessive or fluctuating vacuum levels, faulty teat cup liners, incorrect pulsation ratios and other faults attributed to inadequate maintenance and careless use of milking machines have been shown to cause teat injury. A high milking vacuum combined with a relatively low pulsation chamber vacuum can result in bruising and hemorrhage of the teat end teat wall by the slapping action of the liner.

Black spot (black pox) is a sporadic lesion of the teat tip characterized by a deep, crater-shaped ulcer with a black spot in the center. Lesions occurring at the ends of the teats commonly involve the teat sphincter. This abnormality is caused in most cases by excessive vacuum pressure or overmilking in teats that are naturally firm and have pointed ends. There is no specific bacteriology, although Fusobacterium necrophorum is commonly present and S. aureus is frequently isolated from the lesions. The latter occur only on the teats and take the form of deep, crater-shaped ulcers with raised edges and a black spot in the center. The lesions are confined almost entirely to the tip of the teat, usually invade the sphincter and are responsible for a great deal of mastitis. Lesser lesions of teat sphincters are listed under vacuum pressure in bovine mastitis control.

The lesions are painful, leading to kicking by the cows, sometimes repeated kicking off of the teat cups, and to blockage of the sphincter. Arancobacterium pyogenes mastitis is a common sequel.\(^3\) The lesions are poorly responsive to treatment even if the machine error is corrected.

Treatment of black spot is usually by topical application of ointments Whitfield's, 10% salicylic acid, 5% sulfathiazole and 5% salicylic acid, 5% copper sulfate are all recommended. An iodophor ointment, or iodophor teat dip with 35% added glycerol, is also effective but treatment needs to be thorough and repeated and milking machine errors need to be corrected.

Theletis or inflammation of the tissues of the teat wall leading to gangrene is a common complication of gangrenous mastitis, most commonly associated with peracut S. aureus mastitis. The skin of the teats is cold, edematous and oozes serum. The subcutaneous aspects are commonly distended with gas. The skin is commonly dark-red to purple-black. Sloughing of the skin may be evident.

Inflammation of the wall of the teat (theletis) is a nonspecific lesion usually associated with traumatic injury to the lining of the teat cistern. The wall of the cistern is thickened, hardened, painful and, in chronic lesions, irregular in its internal lining. The lesion can be felt as a dense, vertical cord in the center of the teat tip. The lesions have historically been intractable to treatment, which usually consists of intramammary antibiotics and refraining from milking. The recent application of teat endoscopy has assisted in identifying cattle that are most likely to respond to medical or surgical treatment.

Enzootic nodular theletis of alpine cows in Switzerland\(^4\) is characterized by nodular lesions in the teat wall. The lesions are multicentric nodules containing atypical mycobacteria. A similar disease in French cattle is characterized by tubercloid granulomas on the teats and lower udder that contain acid-fast mycobacteria, including Mycobacterium terrae.\(^5\)

Corpora amylacea are inret concretions of amyloid that may become calcified and detached from the mammary tissue so that they cause blockage of the teat canal and cessation of milk flow. They are formed as the result of stasis due to blocked mammary tissue ducts and resorption of the milk fluids.

Papillomatosis of the teats is caused by bovine papillomavirus and is characterized clinically by small, white, slightly elevated nodules of 0.3 cm diameter or elongated tags 1 cm long that are removable by traction.

Pseudocowpox is characterized clinically by painful localized edema and erythema with a thin film of exudate over the edematous area. Vesicle formation is uncommon. Within 48 hours of onset of signs, a small orange papule develops, shortly followed by the formation of an elevated, small, dark-red scab. The edges of the lesion then extend and the center becomes umbilicated; at 1 week the lesion measures approximately 1 cm in diameter. By 10 days the central scab tends to desquamate, leaving a slightly raised cirrinate scab commonly termed a ‘ring’ or ‘horseshoe’ scab. One teat may have several such lesions, which coalesce to form linear scabs. The majority of lesions desquamate by 6 weeks without leaving scars, although occasionally animals develop chronic infection.

Photosensitization of the teats (photosensitive theletis) is a local manifestation of generalized photosensitization but occasionally photosensitive theletis is the first clinical abnormality detected by the producer. There is a characteristic erythema and hardness of the unpigmented or white parts of the lateral aspects of each teat. The medial aspect is soft and cool. The teats are also painful and in the early stages apparently irritable, because affected cows will also stand in ponds or waterholes in such a way that the teats are immersed, and then
rock backwards and forwards. They will also brush the sides of the udder with the hind feet in a way that could suggest the stamping movements of abdominal pain. In cases where the photosensitization is related to the induction of parturition by the administration of corticosteroids, the skin lesions are usually restricted to the teats. In cases due to other causes there are usually obvious lesions of photosensitive dermatitis on the dorsal aspects of the body but confined to the white parts.

**LESIONS OF THE BOVINE TEAT AND UDDER**

Thermal burns of the skin of the udder and teats may occur in mature cattle exposed to grass fires. The hairs of the udder and base of the teats are singed black. Thermal injury to the skin varies from marked erythema of the teats to blistering and necrosis and weeping of serum.

**Bovine herpes mammillitis** is characterized by the formation of variable-sized vesicles, severe edema and erythema of the teat with subsequent erosion of the teat epithelium. The vesicles rupture within 24 hours, and copious serous fluid often exudes from the dermis. Fever and depression are common, particularly in young animals. Scabs form over the lesions by the fourth day and the epithelium is re-established under the scab by the third week, although the trauma of milking may delay healing, especially when secondary infection occurs. Scar formation on recovery is uncommon. Lesions may be present on several teats and the base of the udder.

The epidemiology of infection within a herd is consistent with the presence of carrier animals, which may shed virus during times of stress, particularly in the periparturient period. There is a seasonal incidence of clinical disease that has been related to the activity and presence of insect vectors. 

Experimental studies indicate that transmission requires virus inoculation at or below the level of the stratum germinativum of the teat or udder skin, and therefore trauma associated with milking, teat cracks or biting flies (such as *Stomoxys calcitrans*) is a requirement for infection to be transferred.

Diagnosis is made on the basis of clinical signs in multiple animals. Virus may be isolated from aspirating the fluid from vesicles before they rupture. Serology has been performed in order to identify a three- to fourfold rising titer but is not widely available and many animals seroconvert early in the disease process.

Treatment is general supportive, including the application of topical antiseptics. Cattle that develop a thickened teat due to secondary bacterial infections are likely to develop clinical mastitis and treatment success of affected quarters is poor. Standard control measures for mastitis should be implemented, including isolation of clinically active cases. There is one report that suggested iodine-based teat dips are virucidal and therefore may be of assistance in decreasing transmission.

**LESIONS OF THE BOVINE UDDER OTHER THAN MASTITIS**

**Udder impetigo** associated with *S. aureus* is characterized by small, 2–4 mm diameter pustules at the base of the teats that may spread to involve the entire teat and the skin of the udder. This disease is of importance because of the discomfort it causes, its common association with staphylococcal mastitis, its not uncommon spread to milkers’ hands and the frequency with which it is mistaken for cowpox. The lesions are usually small pustules (2–4 mm diameter) but in occasional animals they extend to the subcutaneous tissue and appear as furuncles or boils. The most common site is the hairless skin at the base of the teats, but the lesions may spread from here on to the teats and over the udder generally. Spread in the herd appears to occur during milking and a large proportion of a herd may become affected over a relatively long period. The institution of suitable sanitation procedures, such as dipping teats after milking, washing of udders before milking and treatment of individual lesions with a suitable antiseptic ointment, as described under the control of mastitis, usually stops further spread. An ancillary measure is to vaccinate all cows in the herd with an appropriate *S. aureus* vaccine, and treatment of individual lesions with a suitable antiseptic ointment, as described under the control of mastitis, usually stops further spread. An ancillary measure is to vaccinate all cows in the herd with an appropriate *S. aureus* vaccine.

What appears to have been an exaggerated form of this disease has been reported in a recently gathered herd of cows. It is assumed that the cows were very susceptible and that the *S. aureus* present was very virulent. In addition to the signs described above, there was a high prevalence of clinical mastitis and a generalized exudative dermatitis reaching from the escutcheon to the thighs.

**Sores of bovine teat skin in Norway** characterized by the presence of *S. aureus* and referred to as ‘bovine teat skin summer sore’ are thought to be caused by cutaneous invasion by *Stephanofilaria* spp. nematodes. The differential diagnosis of discrete lesions on bovine teat skin is dealt with in the subject of cowpox.

**Udder rot (udder cleft dermatitis, flexural seborrhoea)** of cattle occurs most commonly in dairy heifers that have calved recently. Lesions are present in three locations: on the caudodorsalateral aspect of the udder where it comes into contact with the medial aspect of the thigh, between the halves of the udder (udder cleft dermatitis) or on the ventral midline immediately cranial to the udder. Lesions are usually detected during foot trimming or milking. Udder edema is believed to play an important role in development of lesions on the caudodorsalateral aspect of the udder, because these occur most commonly in peri-parturient dairy heifers. In contrast, udder cleft dermatitis occurs most commonly in older dairy cattle and the etiology remains uncertain.

In lesions of all three anatomical sites, there is severe inflammation and a profuse outpouring of sebum. Extensive skin necrosis may develop, characterized by a prominent odor of decay. The irritation and pain of the caudodorsalateral lesions may cause the animal to appear lame when walking, and the animal may attempt to lick the affected part. Shedding of the oily, malodorous skin leaves a raw surface beneath, which heals in 3–4 weeks. Some animals with lesions on the caudodorsalateral aspect of the udder benefit from resolution of udder edema and mechanical debridement using a towel drawn repeatedly across the inguinal area. In advanced cases, a soft tissue curette is used to facilitate debridement of necrotic material. The efficacy of topical treatment is unknown. Lesions in the other two sites are usually asymptomatic.

**Blood in the milk** is usually an indication of a rupture of a blood vessel in the gland by direct trauma (such as getting caught on top of a wooden fence or the result of a kick) or more commonly by capillary bleeding in heifers with udder edema. Although in the latter circumstance the bleeding usually ceases in 2–3 days, it may persist beyond this period and render the milk unfit for human consumption. The discoloration varies from a pale pink to a dark chocolate brown and may still be present 7–8 days after parturition. Randomly, the blood loss may be sufficiently severe to require treatment for hemorrhagic shock (see Ch. 2). Treatment is often requested, although the cow is clinically normal in all other respects. Intravenous administration of calcium borogluconate or parenteral coagulants is widely practiced but efficacy studies are lacking and it is difficult to believe that either treatment has therapeutic value. Difficulty may be experienced in milking the clots out of the teats, but they will usually pass easily if they are broken up by compressing them inside the teat. The presence of blood-
sustained milk in all four quarters at times other than immediately postpartum should arouse suspicion of leptospirosis or diseases in which extensive capillary damage occurs. Cases of blood in the milk are usually sporadic in occurrence but there are records of herds with over 50% of cows affected. No clotting defects were evident.

**UDDER EDEMA**

Edema of the udder at parturition is physiological but it may be sufficiently severe to cause edema of the belly, udder, and teats in cows and mares. In most cases the edema disappears within a day or two of calving, but if it is extensive and persistent it may interfere with sucking and milking. A 10-level scale of severity has been devised and could be applied and milking. A 10-level scale of severity has been devised and could be applied in assessing the effects of treatment (Table 15.6). Edema is a prominent sign in inherited rectovaginal constriction of Jersey cows, and is described under that heading.

**Udder edema is most severe in periparturient heifers**, and the mechanism for its development is not well understood. Hypoproteinemia is not a precursor of udder edema. It is a common recommendation that the amount of grain fed in the last few weeks of pregnancy be limited, and there is evidence that heavy grain feeding predisposes to the condition, at least in heifers. High sodium or potassium intakes increase the incidence and severity of udder edema, especially in housed cattle; the disease often disappears when cows are turned out to pasture. The tendency for udder edema may be heritable in some herds and selection against bulls that sire edematous daughters is thought to be worthwhile. Such a tendency could be mediated through a complex interaction between sex steroids, which are thought to play a role in the etiology. There is also a reduction in blood flow through, and an increase in blood pressure in, the superficial epigastric or milk veins of cows with chronic edema, through an unidentified mechanism.

A mild form of udder edema is the presence of a hard localized plaque along the ventral abdomen immediately cranial to the udder after parturition in heifers. This is common and relatively innocuous but may interfere with milking or ventral abdominal surgical repair of a left displaced abomasum. If the mild udder edema occurs repeatedly over a number of lactations it may result in permanent thickening of the skin (scleroderma) of the lateral aspect of the udder. Hot fomentations, massage and the application of liniments are of value in reducing the hardness and swelling. A chronic form of the disease is recorded from New Zealand but no credible etiological agent has been proposed.

If udder edema is severe, one or more of the following empirical treatments is recommended. Milking should be started some days before parturition, but colostrum from heifers should be discarded as it is likely to be of poor quality. After parturition, frequent milking and the use of diuretic agents is recommended. Corticosteroids appear to exert no beneficial effect. Acetazolamide (1–2 g twice daily orally or parenterally for 1–6 d) gives excellent results in a high proportion of cases, the edema often disappearing within 24 hours. Chlorothiazide (2 g twice daily orally or 0.5 g twice daily by intravenous or intramuscular injection, each for 3–4 d) is also effective. Furosemide is the most potent diuretic agent and should be administered parenterally (1 mg/kg BW, intramuscularly or intravenously; 5 mg/kg BW orally) in severe cases of udder edema, but prolonged use can result in hypokalemia, hypochloremia and metabolic alkalosis. The use of diuretics before calving may be dangerous if considerable fluid is lost. When there is a herd problem, detection of the cause is often difficult.

An outbreak of udder edema in ewes has been recorded. Affected animals were afebrile, bright and clinically normal except for the udder, which within 24 hours of lambing was white, cool, and firm, with edema. The milk was normal grossly and laboratory tests detected no abnormalities. Most ewes recovered within 5–10 days of lambing.

Hard udder or indurative mastitis in goats is described under the heading of caprine arthritis–encephalitis, and that in ewes under maedi.

### Rupture of the Suspensory Ligaments of the Udder

Rupture of the suspensory ligaments occurs most commonly in adult cows and develops gradually over a number of years. The cause is thought to be severe udder edema at calving, with excessive weight on the udder causing breakdown of the udder attachments, particularly the median suspensory ligament. The result is that the teats on affected cows are not vertically aligned but point more laterally. When rupture of the suspensory ligament occurs acutely, just before or after parturition, the udder drops markedly and is swollen and hard, the teats point laterally and serum oozes through the skin. Severe edema occurs at the base of the udder. The condition may be confused with gangrenous mastitis or abdominal rupture due to hydrops allantois on cursory examination. Partial relief may be obtained with a suspensory apparatus but complete recovery does not occur.

### Agalactia

The most important cause of agalactia in farm animals is mastitis–metritis–agalactia (MMA) in sows. The general principles that apply there apply also to the less common cases of agalactia that occur in all species. There is partial or complete absence of milk flow, which may affect one or more mammary glands. The condition is of major importance in gilts and sows, although it occurs occasionally in cattle. The importance of the disease in gilts and sows derives from the fact that piglets are very susceptible to hypoglycaemia. The condition may be due to failure of letdown or absence of milk secretion.

The causes of failure of letdown include painful conditions of the teat, sharp teeth in the piglets, inverted nipples that interfere with sucking, primary failure of milk ejection, especially in gilts, and excessive engorgement and edema of the udder. In many sows the major disturbance seems to be hysteria, which is readily cured by the use of tranquilizing drugs. Treatment of the primary condition and the parenteral administration of oxytocin, repeated if necessary, is usually adequate.

**Ergotism** may be a specific cause of agalactia in sows and has been recorded in animals fed on bullrush millet infested with ergot.
Apparent hormonal defects do occur, particularly in cattle. Sporadic cases occur in which cows calve normally and have a normal udder full of milk but fail to let it down when stimulated in the normal way. A single injection of oxytocin is often sufficient to start the lactation. In rare cases repeated injections at successive milkings are required. There is one report of a number of cows in a herd being affected.\(^2\) The cows were under severe stress for a number of reasons and had depressed serum cortisol levels. In heifers and gilts there may be a complete absence of mammary development and, in such cases, no treatment is likely to be of value. In animals that have lactated normally after previous parturitions, the parenteral administration of chorionic gonadotrophin has been recommended but often produces no apparent improvement.

Mares grazing fescue may fail to lactate after parturition because of inhibition of prolactin release.

Milk drop syndrome

This is a herd syndrome in which the milk yield falls precipitously without there being any clinical evidence of disease, especially mastitis, or obvious deprivation of food or water. Heat stress (particularly the combination of heat and humidity), summer fescue toxicosis and leptospirosis due to Leptospira hardjo are among the more common causes.

‘Free’ or ‘stray’ electricity as a cause of failure of letdown

Free electrical current is common in dairies, especially recently built ones. The problem is most common when a herd moves into a new shed but it also occurs with alterations to electrical equipment and wiring or with ordinary wear and tear to it. The stray current is present in the metallic part of the building construction, much of which is interconnected. Cows are very sensitive to even small amperages and are highly susceptible because they make good, often wet contact with the metal and with wet concrete on the floor. People working in the dairy are not likely to notice the electrical contact because they are usually wearing rubber boots. The voltage present would be too low to be of much interest to the local power authority, and an independent technician may be necessary to carry out the examination, which should be carried out while the milking machine is working. The effects of free electricity in the milking shed may be:

- Restlessness, frequent urination, defecation, failure to let milk down, in tie-stalls frequent lapping at the water bowl but refusing to drink. The abnormal behavior may be apparent only when the cow is in a particular position or posture
- Startled, alert appearance with anxiety, baulking, refusal to enter the milking parlor
- Failure of letdown leads to lower milk production and recrudescence of existing subclinical mastitis leading to appearance of clinical signs.

In spite of the many field observations of these abnormalities experimental application of AC current up to 8 mA causes changes in behavior but not in milk yield or letdown.\(^3\)

Recommended guidelines for a diagnosis of free electricity problems are set out in Table 15.7.\(^4\) For simplicity it can be assumed that cows will behave abnormally if the free voltage exceeds 1 V AC, although 2 V and a current of 3.6–4.9 mA does not reduce milk production.\(^5\) A safer threshold is 0.35 V AC as a maximum.\(^6\) A proper voltmeter is necessary to make a diagnosis and in most circumstances a qualified electrician is necessary for the exercise.

The development of voltages in the metalwork of the milking shed can arise from many factors. Obvious short circuits from faulty wiring are the least common cause. Most cases are due to accumulation of relatively low voltages because of increased resistance in the earth or ground system, thus neutral to earth voltages. Reasons for the accumulation include a poor earthing or grounding system, grounding rods that are too short, a poorly maintained earthing system, grounding rods that are too short, a poorly maintained earthing system, and in most circumstances a qualified electrician is necessary for the exercise.

The problem may be intermittent and even seasonal, depending on climatic conditions that facilitate the passage of current through the cow as an alternative grounding system.

NEOPLASMS OF THE UDDER

Neoplasms of the bovine udder are particularly rare and have moderate malignancy.\(^7\) A fibrosarcoma originating within or close to a mammary gland has been observed to have high malignancy.\(^8\)

Primary teat fibroma and fibrosarcoma in heifers have been satisfactorily treated by surgical excision.\(^9\) Malignant mammary carcinoma occurs occasionally in mares.\(^10\) A mammary adenocarcinoma and ovarian granulosa cell tumor have been recorded in an aged Toggenburg goat.\(^11\) Neoplasms of the skin of the udder may spread to involve mammary tissue.

The commonest neoplasm of cows' teats is viral papillomatisis. It is esthetically unattractive and may play a part in harboring mastitis organisms on the teat skin. It is dealt with in detail under the heading of papillomatisis. Similar papillomatisis occur on the teat and udder skin of lactating Saanen goats. Rarely, these lesions may develop a squamous-cell carcinoma lesion of low malignancy.\(^12\)

TEAT AND UDDER CONGENITAL DEFECTS

The common sporadic defects in cows are supernumerary teats, fused teats with two teat canals opening into one teat sinus, hypomastia, absence of a teat canal and sinus\(^13\) and absence of a connection between the teat sinus and the udder sinus; in sows insufficient and inverted teats are the common errors. Supernumerary teats are common (up to 33%) in Simmental and Brown Swiss heifers and are removed surgically.\(^14\) A high prevalence of defects is recorded in Murrah buffaloes\(^15\) and inheritance of hypomastia, rudimentary teats and angulation of teats is suspected in cows.\(^16\)

Traditionally sows are required to have at least 12 functional teats\(^17\) and sows deficient in this regard are likely to be culled. Reasons for the deficit include inherited shortage (teat number is highly heritable), misplaced teats (usually too far posteriorly to be accessible to the piglets) or unevenly placed, inverted teats, either congenital or acquired as a result of injury, vestigial nipples that do not acquire a lumen, cistern or gland, and normal-sized teats that are occluded. Inverted teats in sows may be so because they lack a teat upturn, the teat duct opening directly into the mammary gland cistern.\(^18\)

Mastitis—metritis—agalactia syndrome in sows

The mastitis—metritis—agalactia (MMA) syndrome (also called toxemic agalactia, farrowing fever, lactation failure, periparturient hypogalactia syndrome (PHS), or postpartum dysgalactia syndrome (PPDS)) occurs in sows between 12 and 48 hours (sometimes 72 h) after farrowing and is characterized clinically by anorexia, lethargy, restlessness, lack of interest in the piglets, fever, swelling of the mammary glands and agalactia. Most affected animals respond to therapy within 12–24 hours. Pathologically, there are varying degrees of mastitis. In some sows the level of oxytocin may be half the level in unaffected sows. The disease is of major economic importance when outbreaks occur because the inadequate milk production leads to high piglet mortality from starvation and secondary infectious diseases. In cases of subclinical MMA there is often a failure to achieve weaning weights (< 4 kg at 24 d). The term mastitis—agalactia was originally developed to describe sows with agalactia that had swollen udders, assumed to be due to mastitis, and the appearance of a vulval discharge, assumed to be due to metritis. Necropsy of spontaneously occurring cases has frequently confirmed the presence of mastitis but the incidence of metritis has been insignificant.

The prevalence of the condition appears to have increased recently with the increased attention to hygiene in the farrowing house and the use of more porous and less traumatic floors. When it does occur it can be quite common, with up to 11–58% of the sows being affected.1

A recent case definition2 suggests that the pathognomonic signs are poor piglet growth and sow rectal temperatures greater than 39.5°C.

ETIOLOGY
The etiology is unclear. Several different cause-and-effect relationships have been proposed, based on clinical and epidemiological observations, but only infectious mastitis has been substantiated. The list of proposed causes includes infectious mastitis, metritis, overfeeding during pregnancy, nutritional deficiencies, constipation and endocrine dysfunction. The composite view of this is that there are potential sources of bacterial infection with subsequent endotoxin absorption that lead to the subsequent systemic signs. There is a very considerable farm effect in the appearance of the condition as sow care and management are so important.

A major problem in the determination of the etiology is the difficulty of being precise in the description of the clinical findings of the abnormal mammary glands of affected sows. The common clinical findings are:

- Swelling of the glands
- Agalactia
- Toxemia
- Fever.

There is considerable overlap in the clinical findings from one affected sow to another but the lesion present in the mammary glands may vary from uncomplicated physiological congestion and edema to severe necrotizing mastitis.

Ringarp3 published the classic work on this disease based on 1180 cases of postparturient illness in sows in which agalactia was present. At least five causes of agalactia or hypagalactia were recognized which are as follows (the incidence of each group as a percentage of the total cases is given in brackets):

- Eclampsia (0.6%), usually of older sows, responding to calcium and magnesium therapy
- Failure of milk ejection reflex (3.3%), affecting primarily first-litter gilts and usually treated satisfactorily with oxytocin
- Mammary hypoplasia (1.5%) in gilts, resulting in deficient milk secretion
- Primary agalactia (6%), in which reduced milk supply is the only abnormality
- Toxic agalactia (88.6%), the most important numerically and economically. It is characterized by anorexia, depression, fever, swelling of the mammary glands and a course of 2–4 days. Mastitis was commonly present but there was no evidence of metritis.

Infectious mastitis is suggested as a major cause in many clinicopathological investigations and there is a greater incidence of intramammary infection in affected sows compared to normal sows. Peracute mastitis in sows is readily recognized as a clinical entity but less severe infections may result in small foci of inflammation within the gland that cannot be detected on clinical examination.

Escherichia coli and Klebsiella pneumoniae have been recovered from the mammary glands of naturally affected cases and both bacterial species are associated with histopathological changes of mastitis. Experimental intramammary inoculation of sows with field isolates of E. coli and K. pneumoniae has resulted in cases of lactation failure and mastitis that closely resemble naturally occurring cases. Unfortunately, they cannot always be demonstrated in the plasma of affected sows and neither can endotoxin. Streptococcus spp. and Staphylococcus spp. have also been isolated, but these are frequently isolated from healthy glands unassociated with pathological changes. It is unlikely that Mycoplasma spp. are important.

Coliforms are the most significant pathogens isolated from sows with mastitis. Pathological examination of affected sows that were euthanized within 3 days after parturition revealed the presence of varying degrees of mastitis, and E. coli and Klebsiella spp. were the most common organisms recovered. A recent study has shown that E. coli strains from mastitis in sows are highly variable in serotype, biochemical profile, virulence factors and random amplified polymorphic DNA (RAPD) type. No relationship between serotypes, virulence factors and RAPD types was found.5 Toxic agalactia can be produced experimentally by the introduction of E. coli endotoxin into the mammary gland of sows at parturition. The clinical, hematological, and serum biochemical changes are similar to those that occur in naturally occurring cases of

toxic agalactia. *E. coli* endotoxin acting at the level of the hypothalamus can suppress prolactin release, which results in a pronounced decline in milk production. Experimental *Klebsiella* mastitis in sows is an excellent model for the study of toxic agalactia due to infectious mastitis.

Agalactia may also be the result of a deficiency of prolactin. Prolactin levels may be dramatically reduced by even the smallest amounts of endotoxin. Any factor that interferes with the release of prostaglandin from the uterus may affect the increase in prolactin that must occur to stimulate lactogenesis immediately prior to parturition. In summary, field observations have suggested many different causes and predisposing factors, including infectious mastitis, nutritional disturbances, metabolic disorders and the stress of farrowing in total confinement in a crate. Based on the examination of spontaneously occurring cases, infectious mastitis appears to be a major cause. Both prolactin and oxytocin release can be stopped by stressors and toxins from bacteria such as *E. coli*.

**EPIDEMIOLOGY**

**Occurrence**

The disease occurs most commonly in sows at farrowing or within the first 48 hours after parturition. It is most common in sows that farrow in crates indoors and only occasionally occurs in sows farrowing outdoors, which may be a reflection of the greater number of pigs raised in confinement. A peak incidence during the summer months has also been observed. The disease will often occur in one batch and then disappear again for months, which suggests that some unidentified factor may be affecting a whole group.

**Morbidity and case fatality**

Morbidity and mortality data are not readily available nor precise because of the difficulty of making a reliable clinical diagnosis. Epidemiological observations indicate that the risk of sows developing toxic mastitis increases with increasing age up to the third or fourth litter. The population incidence of toxic agalactia ranges from 4–10% of all farrowings while the herd incidence may vary from 0–100%. Some surveys report an overall incidence of 6.9% of all farrowings with a range from 1.1% to 37.2%. The incidence rates in Swedish herds ranges from 5.5% in small herds to 10.3% in large herds. In Denmark, an incidence rate of 9.5% from a total of 80,000 farrowings, independent of herd size, has been reported. In a survey of 70 herds in Norway over a period of 2 years, the incidence rate was about 17.5% and there was no consistent relationship between disease incidence and herd size. Sporadic outbreaks of the disease may occur in which almost all sows farrowing over a period of several weeks or a few months may be affected and then suddenly no further cases develop for no apparent reason.

The fatality rate is usually less than 2%, but piglet losses due to starvation and crushing may be as high as 80%. It is not a major cause of sow mortality. The disease does not usually recur in the same animal, which may suggest that immunity develops and possibly that affected sows should not necessarily be culled because of the disease.

**Risk factors**

The risk factors that have been proposed based on field observations include overfeeding during pregnancy, a drastic change of feed at farrowing, insufficient time for the sow to adjust to the farrowing crate after being transferred from the gestation unit and constipation of the sow at farrowing.

Animal risk factors

The initiating factors have not been identified. The incidence of the disease may also be higher in sows with larger litters than sows in the same herd that remain healthy, and in those with a higher number of stillbirths and pigs found dead after birth.

Each section of the mammary gland of the sow is divided into a separate anterior and posterior section, each with its own teat cistern and teat canal. In a sow with 14 teats there are 28 potential portals of entry for environmental infectious agents and perhaps it is little wonder that mastitis should occur commonly immediately after parturition when the teat canals have become patent. Bacteria in the gut and in endometritis have been proposed as a source of endotoxin, particularly as *beta-hemolytic streptococci* and coliforms have been associated with the condition.

Some clinicopathological examinations of affected sows have revealed the presence of a slightly enlarged, flaccid uterus from which coliform and streptococcal organisms can be recovered. However, pathological evidence of metritis in affected sows is uncommon; the organisms that can be recovered are commonly present in the reproductive tract of normal sows after parturition and their recovery from vaginal mucus is difficult to interpret.

Constipation of sows at farrowing time has been suggested as a cause but has not been substantiated. However, clinical and pathological examinations of both spontaneously occurring cases of agalactia and experimental agalactia induced by the introduction of *E. coli* endotoxin into the mammary gland have been unable to support the observation of constipation. Both sick and normal sows defecate less frequently from 1 day before farrowing until 2 days later. There is no difference in the weight of feces in the terminal colon and rectum between sick and normal sows. Low exercise has also been suggested as a cause and this also contributes to constipation. The role of water intake or lack of it and stress or disturbance during parturition has also not been investigated.

The nursing behavior of the sow and the sucking behavior of the piglets may provide an explanation for the pathogenesis and clinical findings of some cases of agalactia in sows. Successful ejection of milk by the sow is dependent on proper stimulation of the sow's udder by the piglets followed by a complex response by the sow. A period of time ranging from 15–45 minutes must elapse from the last successful milk ejection to the next. Failure of milk ejection may occur in up to 27% of sows that attempt to suckle their piglets within 40 minutes after the previous milk ejection. The failure of milk ejection in sows within the first few crucial adjustment days after farrowing might possibly contribute to the cause of mastitis and engorgement of the mammary glands. The possible causes of failure of milk ejection, even when a suitable interval has elapsed since the previous milk ejection, include:

- Environmental or other animal noises and disturbances
- Uncomfortable farrowing crates
- High environmental temperatures
- Insufficient time to adjust to the farrowing crate.

**Management and dietary factors**

The disease occurs under management, environmental and sanitation conditions ranging from very poor to excellent; however, the possible relationship between the level of bacterial contamination in the farrowing barn and on the skin of the sow and the incidence of the disease has apparently not been examined. Dirty conditions greatly increase the bacterial contamination of the udder.

Digestive disturbances and certain feeding practices have been associated with the disease. Sows that have been on high-level feeding during pregnancy appear to be susceptible to the disease, especially if they are subjected to a change of feed immediately prior to parturition. Also, any management practice that results in a marked change in feed intake at or near farrowing may appear to precipitate the disease. A sudden change of feed severe enough to result in gastrointestinal stasis has
been used to reproduce the condition experimentally.

The effects of different feed allowances during late pregnancy may affect the incidence rate of the disease. Feeding sows during the last 15 days of gestation a diet at a level of 3.4 kg daily compared to 1.0 kg daily resulted in an incidence rate of 26.6% and 14.0%, respectively. The explanation for the effects of feeding is unknown. It has been proposed that intense feeding may promote toxin production in the alimentary tract but how this is related to mastitis is unknown. Another hypothesis suggests that increased feeding in late gestation may intensify the initiation of lactation and result in udder engorgement and increased susceptibility to intramammary infection. A further suggestion is that moldy food may play a part, but this has never been proved.

The clinical status of the mammary glands, the bacteriological findings and the total cell count and its percentage of polymorphonuclear leukocytes and pH in colostrum and milk secretion during the first 3 weeks of lactation of sows on high or low feeding regimes during late pregnancy have been examined. E. coli infection was present in 80% of the sows affected with toxic agalactia and 30% of the healthy sows. The E. coli were eliminated at between 3 and 8 days of lactation and were not isolated from sows examined at the time of weaning. The different feeding regimes did not influence the total cell count, the polymorphonuclear cells or the pH in milk from bacteriologically negative glands or glands with E. coli mastitis. The two feeding regimes had no influence on total cell count, the percentage of polymorphonuclear cells or the pH of colostrum and milk of healthy sows.

**PATHOGENESIS**

The pathogenesis of infectious mastitis due to E. coli or Klebsiella spp is probably similar to that of bovine mastitis in which the infection gains entry through the teat canal and invades the mammary tissue causing mastitis. Endotoxemia occurs accounting for the fever initially, and the depression, anorexia and agalactia, even in glands that are unaffected. The lipopolysaccharide endotoxins acting at the level of the hypothalamus and hypophysis suppress the release of prolactin which results in a marked decline in milk production. The endotoxin may also have a direct inhibitory effect on the mammary gland. There is a higher prevalence of bacterial endotoxin in the blood of affected sows compared to control animals. The endotoxin can be detected in the blood of about 33% of sows affected with coliform mastitis. However, the oral administration of endotoxin daily to prepubertal gilts did not result in any clinical abnormalities. Experimentally, mastitis can be produced in sows by contamination of the skin of the teats with K. pneumoniae either shortly before or after parturition. The clinical signs are similar to those described for MMA: mastitis is present in more than 50% of the mammary gland subsections and a marked leukopenia and degenerative left shift occurs. A total of 120 organisms is sufficient to produce the mastitis when the organisms are inoculated into the teats. In recent experimental infections with E. coli it was shown that the time of infection of the mammary gland relative to parturition and the number of circulating neutrophils at the time of infection influenced the development of clinical coliform mastitis in the sow. Similarly parturition allows the penetration of vaginal organisms further up the reproductive tract and the absorption of endotoxin reduces F2α in the uterus and this stimulates prolactin, which may contribute to the hypogalactia and agalactia.

If noninfectious acute painful swelling of the mammary glands accompanied by agalactia occurs in the sow as a result of the possible noninfectious factors that were described earlier, the pathogenesis is unclear. It is difficult to synthesize a pathophysiological mechanism that would explain how stress, overfeeding, changes in diet or constipation could result in acute swelling of the mammary gland in sows.

**CLINICAL FINDINGS**

Sometimes there may be a delay in parturition of more than 5 hours. The sow is usually normal, with a normal milk flow, for the first 12–18 hours after farrowing. Normally, the sow will suckle her piglets for about 20 seconds once an hour. One of the first indications of the disease is the failure of the sow to suckle her piglets. She is uninterested in the piglets, generally lies in sternal recumbency and is unresponsive to their squealing and suckling demands. Litters of affected sows are more noisy and are generally scattered around the pen searching for an alternative food supply. Such piglets may drink surface water or urine in the pen and infectious diarrhea may occur. If suckling is permitted, it does not progress from the vigorous nursing phase to the quiet letdown stage, and it is accompanied by much teat-to-teat movement by the piglets. Many piglets may die from starvation and hypoglycemia. A failure to grow at more than 105 g/d is a sure sign of piglet problems. Some sows are initially restless and stand up and lie down frequently, which contributes to a high mortality from crushing and trampling.

Affected sows do not eat, drink very little and are generally lethargic. The body temperature is usually elevated and ranges from 39.5–41°C (103.1–105°F), especially if there is mastitis. Mild elevations in body temperatures of sows in the first 2 days after parturition are difficult to interpret because a slight elevation occurs in normal healthy sows. This is known as uncomplicated farrowing fever. However, temperatures above 40°C (104°F) are usually associated with acute mastitis that requires treatment. One detailed investigation of the disease in Sweden concluded that 78% of sows with a temperature exceeding 39.5°C had clinical evidence of mastitis. It is suggested that a temperature of 39.4°C at 12–18 hours after farrowing is an appropriate threshold at which to give preventive treatment for the disease. The heart and respiratory rates are usually increased.

Initial temperatures greater than 40.5°C (104.9°F) are usually followed by severe illness and toxemia. Normally, the sows get better within 3 days, but not always if the temperature is very high.

The characteristic findings are present in the mammary glands and consist of varying degrees of swelling and inflammation. In most cases, several sections are affected, which results in the appearance of diffuse involvement of the entire udder. Individual sections are enlarged, warm and painful, and may feel ‘meaty’ and lack the resilience of normal mammary tissue. There may be extensive subcutaneous edema around and between each section, which results in a ridge of edema on the lateral aspects of the udder extending for its entire length. The skin overlying the sections is usually reddened and is easily blanched by finger pressure. The teats are usually empty and may be slightly edematous. A few drops of milk may be expressed out of some teats after gentle massage of the section or the administration of oxytocin but rarely can a normal stream of milk be obtained. In severe cases of mastitis the milk contains flakes and pus or is watery.

The feces are usually scant and drier than normal but whether or not constipation is present in most cases is uncertain. The inappetence and anorexia and failure to drink normally could account for the reduced volume of feces. Constipation with impaction of the rectum with large quantities of feces is uncommon in sows and when it does occur as the only abnormality it has little effect on appetite and milk production.

A vaginal discharge is normal following parturition, and normal sows frequently expel up to 50 mL of a viscid, nonodorous,
clear mucus that contains variable amounts of white material within the first 3 days following farrowing. Tenacious strands of this discharge may also be observed within the vagina. The presence of this discharge has been misleading and has been interpreted as evidence of the presence of metritis. Necropsy examination after euthanasia of affected sows has failed to reveal evidence of significant metritis. The clinical diagnosis of metritis in sows is difficult but generally large quantities of dark-brown, foul-smelling fluid are expelled several times daily, accompanied by severe toxemia. This is uncommon in sows. Diagnosis is usually on clinical signs.

**CLINICAL PATHOLOGY**

**Examination of milk**

The number of somatic cells in the milk from sows with mastitis will range from 2-20 × 10^6/mL compared to the normal of less than 2 × 10^5/mL. Significant numbers of bacteria are present in the milk of more than 80% of sows with toxic agalactia. Milk obtained for laboratory examination and culture should be taken after thorough cleaning and disinfection of the teats to minimize contamination by skin flora. However, because mastitis may be present in only one or a few of the mammary gland subsections in the sow and because it is often impossible to clinically identify affected subsections and distinguish them from unaffected adjacent glands, which may be swollen and agalactic because of continuous swelling, a valid assessment of intramammary infection is not possible unless milk samples are obtained from each subsection. Subclinical mastitis may not be easy to detect with cells not reaching 2 × 10^5/mL but 75% may be polymorphs. Normally, milk is around 1 × 10^5/mL.

**Hematology and serum biochemistry**

Some hematological and biochemical changes are present in affected sows but may not be marked enough to be a routine reliable diagnostic aid. In severe cases of infectious mastitis, a marked leukopenia with a degenerative left shift is common. In moderate cases there is a leukocytosis and a regenerative left shift. The serum biochemical changes that occur in naturally occurring cases and in the experimental disease are recorded. The plasma cortisol levels are commonly elevated, which may be due to a combination of the stress of parturition and infectious mastitis. The plasma protein-to-fibrinogen ratio is lower than normal and the plasma fibrinogen levels are commonly increased in severe cases that occur 8–16 hours after parturition.

**NECROPSY FINDINGS**

Neither lesions in the udder nor the reproductive tract are consistent. If they are found, the most important lesions are in the mammary gland. There may be extensive edema and some slight hemorrhage of the subcutaneous tissue. Grossly, on cross-section of the mammary tissue there is focal to diffuse reddening and often only one subsection of a mammary gland may be affected. Histologically, the mastitis may be focal or diffuse in distribution and the intensity of the lesion varies from a mild catarrhal inflammation to a severe purulent and necrotizing mastitis usually involving more than 50% of all the mammary glands. There are no significant lesions of the uterus when compared with the state of the uterus in normal healthy sows immediately after parturition. The adrenal gland is enlarged and heavier than normal, presumably due to adrenocortical hyperactivity. In a series of spontaneous cases, E. coli and Klebsiella spp. were most commonly isolated from the mammary tissues. The abscesses of the mammary glands of sows examined at slaughter are not sequelae to coliform mastitis but rather probably due to injuries and secondary infection.

**Samples for confirmation of diagnosis**

- Bacteriology – mammary gland, regional lymph node
- Histology – formalin-fixed mammary gland

### DIFFERENTIAL DIAGNOSIS

The characteristic clinical findings in toxic mastitis and agalactia are a sudden onset of anorexia and lack of interest in the piglets, acute swelling of the mammary gland, hypogalactia or agalactia, a moderate fever and a course of about 2 days. The mammary secretion from mastitic glands may be watery or thickened and contain pus, and the cell count will be increased up to 20 × 10^6/mL. The acute swelling and agalactia of infectious mastitis must be differentiated from other non-infectious causes of acute swelling or ‘caking’ of the mammary glands, which also results in agalactia as follows:

- **Agalactia due to a failure in milk letdown** is most common in first-litter gilts and is characterized by a fullness of the mammary glands but an inability of the gilt to suckle her piglets in spite of her grunting at them. The gilt is usually bright and alert and systemically normal. The response to oxytocin is dramatic and repeat treatment is rarely necessary.
- **Farrowing fever** is characterized clinically by loss of appetite, inactivity and a body temperature of 39.3–39.9°C (102.7–103.8°F) with minimal detectable changes of the mammary gland.
- **Parturient psychosis of sows** is characterized by aggressive and nervous behavior of the sow after the piglets are born. The sow does not call the piglets and does not allow them to suck. When the piglets approach the sow’s head, she will back away, snap, and make noisy staccato nasal expirations. Some sows will bite and kill their piglets. The mammary gland is usually full of milk but the sow will not let it down. Ataractic drugs and/or short-term general anesthesia are indicated and the response is usually excellent. Some sows need repeated tranquillization or sedation for the first few days until the maternal-neonatal bond is established.
- **Other causes of agalactia** accompanied by enlargement of the mammary gland include inherited inverted teats and blind teats due to necrosis of the teats occurring when the gilt was a piglet. These are readily obvious on clinical examination. The sharp needle teeth of piglets may cause the sow to refuse to suckle her piglets. The sow attempts to suckle but leaps up suddenly, grunting and snapping at the piglets. The piglets squeal and fight to retain a teat, thus causing more damage to the teats, which is obvious on clinical examination. Other causes of agalactia accompanied by systemic illness include retained piglets and infectious disease such as outbreaks of transmissible gastroenteritis and erysipelas. The common causes of agalactia in pigs where there is lack of mammary development include ergotism, immature gilts and inherited lack of mammary development. These are set out in Figure 15.1.

### TREATMENT

Most affected sows will recover within 24–48 hours if treated with a combination of antimicrobials, oxytocin and anti-inflammatory agents. The treatment should begin when the temperature reaches 39.4°C.**

**Antimicrobials** are indicated in most cases because infectious mastitis and metritis are the two most common causes of the disease. The choice is generally determined by previous experience in the herd or region but broad-spectrum antimicrobials are indicated because E. coli and Klebsiella spp. are the most common pathogens involved. They should be given daily for at least 3 days.** Usually ampicillin, tetracyclines, trimethoprim-sulphonamide, or enrofloxacin is used.

As soon as possible after the disease is recognized every effort must be made to restore normal mammary function through the use of oxytocin and warm water massaging of the affected mammary glands.
Oxytocin 30–40 U intramuscularly or 20–30 U intravenously, is given, frequently, to promote the letdown of milk. If there is a beneficial response the piglets should be placed on the sow if she is willing to allow them to suck. This will assist in promoting milk flow. Massage of the mammary glands with towels soaked in warm water and hand milking for 10–15 minutes every few hours may assist in reducing the swelling and inflammation and promote the flow of milk. It will also relieve the pain and encourage the sow to suckle her piglets. Intramuscular injections of oxytocin may be repeated every hour, along with massage of the glands with warm water. Failure of milk letdown or a low response following the use of oxytocin may be due to a reduced sensitivity of the sow to oxytocin during the first week of lactation. In the normal, healthy sow the peak response to oxytocin occurs in the second week of lactation and gradually decreases to a low response at the eighth week.

The use of a long-acting carba oxytocin analog is being explored as a possible substitute for oxytocin. Oxytocin has an effect for about 14 minutes, while the analog has an effect for about 6 hours. Preliminary results of its use in agalactic sows indicate superior results compared to oxytocin.

Anti-inflammatory agents are in common use for their anti-inflammatory effect but are rarely used on their own; flunixin meglumine has been shown to be beneficial and ketoprofen to alleviate pyrexia and endotoxemia. Recently, meloxicam and oxytocin were shown to reduce mortality compared to flunixin only. Plasma cortisol levels are increased in the experimental disease and for this reason may be contraindicated. However, field reports suggest that their use along with antimicrobials and oxytocin provides a better response than when they are not used. Corticosteroids used alone do not appear to prevent the disease or enhance recovery. To be effective they must be used in combination with antimicrobials and oxytocin. Dexamethasone at the rate of 20 mg intramuscularly daily for 3 days for sows weighing 150–200 kg has been recommended.

Supplementation of piglets
The hypoglycemic piglets must be given a supply of milk and/or balanced electrolytes and dextrose until the milk flow of the sow is resumed, which may take 2–4 days, and most important of all must be kept warm until body reserves are re-established. Piglets should receive 300–500 mL of milk per day divided into hourly doses of 40–50 mL given through a 12–14 French plastic tube passed orally into the stomach. A solution of balanced electrolytes containing 5% glucose can also be given for 1–2 days if a supply of cows’ milk is not available. Condensed canned milk diluted with water 1:1 is a satisfactory and readily available supply of milk. In severe cases where the return to milk production and flow are unlikely, the piglets should be fostered on to other sows. If these are unavailable, the use of milk substitute fortified with porcine gammaglobulin is recommended to prevent the common enteric diseases. This is discussed under colibacillosis. Many more piglets are treated for diarrhea when the sows are treated for MMA, perhaps up to 19% compared to up to 9% normally.1

CONTROL
It has been difficult to develop a rational approach to control because the disease has been considered to be a complex syndrome caused by several different factors. However, the control of infectious mastitis would seem to be of major importance. The routine use of antibiotics and oxytocin without indication does not appear to be helpful.24 Farrowing crates should be vacated, cleaned, disinfected and left vacant for a few days before pregnant sows are transferred from the dry sow barn and placed in the crates. Pregnant sows should be washed with soap and water before being placed in the crate. Farrowing crates must be kept clean and hosed down if necessary, particularly a few days before and after farrowing to minimize the level of intramammary infection. In problem herds, it may be necessary to wash and disinfect the skin over the mammary glands immediately after farrowing. All in/ all out in the farrowing area with proper cleaning and disinfection facilitated by batch farrowing will reduce the disease. An opportunity for exercise will help, as under outdoor conditions (sows in paddocks) the condition is rare.

To minimize the stress to the sow of adjusting to the farrowing crate and the farrowing facilities, the sow should be placed in the crate at least 1 week before the expected date of farrowing. The nature and composition of the diet fed to the sow while in the farrowing crate should not be changed. In order to minimize the risk of toxic agalactia, it is recommended that the daily feed allowance be related to body condition score. It may be necessary to reduce the feed to
1 kg/day (from 100 d gestation) before farrowing. The daily intake (compared to the intake during the dry period) may be increased on the day after the sow has farrowed and in increments thereafter as the stage of lactation proceeds. The inclusion of bran at the rate of one-third to one-half of the total diet for 2 days before and after farrowing has been recommended to prevent constipation. In some herds the use of lucerne meal or other vegetable protein at the rate of 15% of the diet may help control the disease. However, under intensified conditions it may be impractical to prepare and provide these special diets on a regular basis. While field observations suggest that a bulky diet at the time of farrowing will minimize the incidence of toxic agalactia, there is little scientific evidence to support the practice.

Antimicrobial agents used prophylactically have apparently been successful in controlling some outbreaks. A trimethoprim-sulfadimidine and sulfathiazole combination at 15 mg/kg in feed from day 112 of gestation to day 1 after farrowing may reduce the prevalence. Using oxytetracycline early may also help. In a recent study where E. coli, streptococci and staphylococci were the most cultured pathogens, marbofloxacin (10% solution) was found to be superior to amoxicillin. All E. coli, were susceptible to the former but 32% were resistant to the latter antibiotic.

The use of prostaglandins for the induction of parturition in sows has not been associated with a marked consistent change in the incidence of the disease. Some field trials have shown a reduction, while others have had no effect.

**Mastitis of sheep**

**ETIOLOGY**

Most cases (80–90%) of clinical mastitis are due to *Staphylococcus aureus*, the remainder to *Streptococcus agalactiae* and *M. haemolytica*, with rare occurrences of *Escherichia coli* and *Histophilus somni* (formerly *Histophilus ovis*). Coagulase-negative staphylococci are a major cause of subclinical mastitis in sheep. Sheep at pasture are the only species other than cattle in which outbreaks of mastitis due to *S. aureus* and *M. haemolytica* occur. A small percentage of cases are associated with *Clostridium perfringens A, Pseudomonas spp.*, or *Corynebacterium pseudotuberculosis*. *Acholeplasma oculi* is pathogenic and can cause mastitis and agalactia. *Mycolo­plasma serogroup II* is pathogenic in sheep when inoculated experimentally.

**EPIDEMIOLOGY**

Occurrence

Clinical mastitis in ewes occurs about equally immediately after weaning or close to parturition. In pastured ewes the prevalence is low and due usually to *M. haemolytica* or *Staphylococcus* spp. In housed ewes many cases are due to teat injury, especially when the sheep are housed on abrasive floors, such as expanded metal.

Up to 10% of ewes used for milk production have subclinical mastitis. Clinical mastitis in pastured ewes averages only about 2% per year, but mastitis causes up to 10% of all ewe deaths.

The forms of loss in milk sheep are the same as those for dairy cattle. In meat and fiber sheep the losses take the form of deaths, due usually to gangrenous mastitis, and to decreased growth in the neonates. Where sucking lambs have access to supplemental feed the effect of subclinical mastitis on lamb performance is negligible.

Although in most European countries sheep are used for mutton and wool production, in Greece nearly all ewes are milked commercially for the production of Greek feta cheese. Any factor that adversely affects the quantity and quality of ovine milk is of great financial interest. The prevalence of subclinical mastitis in sheep in Greece varies between flocks from 29–43%. Coagulase-negative staphylococci and *S. aureus* were isolated in 44% and 33% of the positive milk samples, respectively.

**Staphylococcal mastitis**

The most prevalent mastitis pathogen of the ewe is *S. aureus*. The incidence of clinical mastitis may be as high as 20%, the mortality rate varies between 25% and 50%, and affected quarters in surviving ewes are usually destroyed. Chronic mastitis can result in a 25–30% reduction in milk yield from affected udder halves. The disease can be a very important one in those countries in which ewes' milk is a staple article of diet. The disease is probably spread from infected bedding grounds, the infection gaining entry through teat injuries caused by sucking lambs.

Other staphylococcal mastitides in ewes include *Staphylococcus epidermidis*, many clinically normal quarters show a high rate of infection with coagulase-negative staphylococci. Experimental infection with *Staphylococcus chromogenes* causes clinical mastitis, *Staphylococcus simulans* causes subclinical mastitis and *Staphylococcus xylosus* causes a transient increase in the SCC.

**Streptococcal mastitis**

The disease can be reproduced by the introduction of *S. agalactiae* into the mammary glands and occurs naturally in sheep used as milking animals. The infection originates from an infected udder and is transmitted to the teat skin of other females by milking machine liners, milkers' hands, wash cloths and any other material that can act as an inert carrier. Also listed as occasional causes are *Streptococcus dysgalactiae* and *Streptococcus uberis*.

**Mannheimia mastitis**

Peracute, gangrenous mastitis associated with *Mannheimia* spp. is the common mastitis of ewes. *M. haemolytica* can be isolated from affected quarters and the disease can be reproduced experimentally by the intramammary infusion of cultures of the organism. *S. aureus*, *Arcanobacterium pyogenes*, and streptococci are often present as secondary invaders.

**Mannheimia* mastitis occurs sporadically in the western USA, Australia, and Europe in ewes kept under systems of husbandry varying from open mountain pasture to enclosed barns. Mastitis is most common in ewes sucking large lambs 2–3 months old. Infection is thought to occur through injuries to teats, perhaps caused by...
overvigorius sucking by big lambs. *Mannheimia* mastitis occurrence is not related to hygiene, many outbreaks occurring in sheep at range but, because of the sheep's habit of sleeping at night on often used bedding grounds, it is possible that transmission occurs by contact with infected soil or bedding.

**PATHOGENESIS**
The mechanisms of pathogenesis are similar to those for bovine mastitis.

**CLINICAL FINDINGS**
In milking ewes clinical mastitis is similar to that in cows, with acute and subacute forms manifested by swelling of the gland and wateriness and clots in the milk. Most clinical cases seen by the veterinarian are in brood ewes, and take the form of gangrenous mastitis, affecting one or both halves.

**Staphylococcal mastitis**
In sheep there is a strong similarity between this form of mastitis and that associated with *M. haemolytica*. They are both peracute, gangrenous infections. The ewe is usually recumbent and profoundly toxic, and the affected gland and the surrounding area of belly wall are blue-green in color and cold to the touch. A few drops of clear, bloodstained liquid is all that can be expressed from the udder. A fatal clinical course of 1–2 days is usual.

**Mannheimia mastitis**
An acute systemic disturbance, with a high fever (40–42°C, 105–107°F), anorexia, dyspnea and profound toxemia, accompanies acute swelling of the gland and severe lameness on the affected side. This lameness is an important early sign and is useful in locating affected animals in a group. The udder is at first hot, swollen and painful and hot and contains watery, brown, flocculent secretion.14

**Caseous lymphadenitis and mastitis**
Suppurative lesions associated with Corynebacterium pseutoduberculosis are found commonly in ovine mammary glands, but they usually involve only the supramammary lymph nodes and are not true mastitis, although the function of the mammary gland may be lost when the infection has spread from the lymph node to mammary tissue.

**Pseudomonal mastitis**
Naturally occurring pseudomonal mastitis in ewes is likely to be gangrenous and lethal18 and accompanied by severe lameness in the hindlimb on the affected side. Infected intramammary infusions or milking machine malfunction19 are the usual means of introducing the infection.

**CLINICAL PATHOLOGY**
Determination of the SCC is useful for the prediction of mammary gland infection in sheep.2 Bacteriologically negative ewe’s milk has 2–3% somatic cells, 10–17% lymphocytes, 10–35% neutrophils and 45–85% macrophages.17 In milking ewes milked by machine, SCCs and CMT scores resemble those in dairy cows.18 However, a universally accepted value has not yet been set for the ewe. The SCC in normal ewes’ milk may range from 500 000–1 000 000 cells/mL. However, more than 95% of milk samples from normal ewes have a total content of less than 500 000 cells/mL. In one survey of milk samples from sheep, mean SCC from mastitis-negative samples was 1500 000 cells/mL.3 All mastitis-positive samples had somatic cells in excess of 2 000 000 cells/mL and it is suggested that the threshold level for subclinical mastitis in ewes should be close to 1 500 000 cells/mL.4 The CMT is a reliable indicator of the SCC of ewes’ milk and of the level of infection, and it, the SCC and the NAGase all correlate well with the microbiological findings in mastitic quarters. Infection with Maedi–Visna virus does not appear to alter milk SCC in the ewe.

**NECROPSY FINDINGS**
The gross appearance of the affected glands varies with the agent involved and the duration of the process.16 In general, the swollen, hemorrhagic, and/or gangrenous nature of fatal acute ovine mastitis is glaringly obvious. A purulent exudate is sometimes present, especially in the case of chronic *C. pseudotuberculosis* infection.

**Samples for confirmation of diagnosis**
Bacteriology – chilled mammary gland for aerobic culture; anaerobic culture if *Clostridium* sp. is suspected.
of pasture areas and culling of affected ewes should also help to control the spread of infection.

Mannheimia mastitis
Polyvalent hyperimmune serum and a formalized vaccine have been shown to be of value in prophylaxis. An autogenous vaccine of killed M. haemolytica appears to confer excellent immunity and should be effective in a flock where the disease is occurring.

REVIEW LITERATURE

REFERENCES

Mastitis of goats
Goats are much less frequently affected by contagious mastitis than cattle, but mastitis is an important sign in many of the infectious diseases associated with Mycoplasma agalactiae and Mycoplasma mycoides var. mycoides. Details of the other infections encountered are fragmentary and inconsistent; coliform organisms, for example, are listed as not occurring and as being most common. Coagulase-negative staphylococci are a common finding in clinically normal halves, and appear to cause persistent infection.

In some surveys, Staphylococcus aureus and Escherichia coli are the most commonly isolated pathogens from mastitic goats. Other infections are Pseudomonas spp., Staphylococcus hyicus (much less pathogenic than S. aureus), Streptococcus dysgalactiae, Streptococcus pyogenes, Streptococcus intermedius, Arcanobacterium pyogenes, Bacillus coagulans, and Bacillus licheniformis. Klebsiella pneumoniae, Corynebacterium pseudotuberculosis, M. haemolytica, and Actinobacillus equuli have also been isolated from mastitic goats. Nocardia asteroides causes a systemic reaction and granulomatous lesions in the udder and lungs.

The prevalence of infection in goats ranges from 10% to 30%. Prevalence of infection in different herds may range from 7–34% of glands and 17–44% of goats.

Staphylococcal mastitis
This is the most common cause of mastitis in goats. In the experimentally produced disease associated with S. aureus in goats the pathogenesis is very similar to that in the cow except that there is a marked tendency for the staphylococci to invade and persist in the interacinar tissue. As in cattle, some staphylococci in goats' milk produce enterotoxins and the toxic shock syndrome toxin and are likely to cause food poisoning in humans. Latex agglutination tests are available for the identification of the enterotoxins.

Streptococcal mastitis
Goats are uniformly susceptible to Streptococcus agalactiae; mastitis associated with it does occur but to a lesser extent than in cattle. In flocks of milking goats the infection is passed from infected quarters to others by means of the milker's hands, the teat cups of milking machines and wash cloths used to disinfect the udder before milking. Streptococcus zooepidemicus causes chronic suppurative mastitis in does, and artificially induced infections with S. dysgalactiae are indistinguishable from mastitis associated with S. agalactiae. The pathogenesis is probably similar in all streptococcal mastitides.

Pseudomonas mastitis
Experimental pseudomonas mastitis in goats is acute, with extensive necrosis and fatal septicaemia.

Summer mastitis
Summer mastitis associated with A. pyogenes has been produced experimentally in goats with udder lesions typical of acute suppurative mastitis. Nonlactating goats developed a severe mastitis, lactating animals only a moderate one.

Other infections
Mastitis in goats is associated with an organism tentatively identified as M. haemolytica. Yersinia pseudotuberculosis has caused mastitis in an aborting goat doe that probably experienced a bout of systemic yersiniosis. The infection would have had zoonotic implications. Granulomatous lesions in the mammary glands and in internal organs have been observed in goats experimentally infected with Cryptococcus neoformans.

CLINICAL FINDINGS
Clinical mastitis in goats is similar to that in cattle, subclinical, chronic, acute and peracute gangrenous forms occurring. Particular care is needed in the clinical examination of goat's milk because of its apparent normality when there are severe inflammatory changes in the udder.

Somatic cell counts in milk of goats
are higher than in cattle or sheep but vary widely. The counts increase with stage of lactation with or without intramammary infection. Lower mature equivalent milk production and increased parity are also associated with an increase. Parity of milking does does not affect SCC, standard plate count and major milk components. The count is highest in lactating goats during October, December and January. Much of the variation was not due to intramammary infection. Non-infected goats may have a SCC of more than 1 000 000 cells/mL. These variations make their value as a guide to diagnosis in this species controversial. A physiological threshold of 500 000 cells/mL has been suggested, however, a count of more than 1 000 000 cells/mL can be regarded as positive for mastitis. Some observations indicate that the most discriminating threshold for diagnosis of infection is 800 000 cells/mL. The Bosomatic instruments and infrared milk analyzers must be calibrated with goat milk standards for more reliable and accurate analysis of milk.

In staphylococcal mastitis infected halves have higher NAGase and CMT tests than normal halves but they and the lactate dehydrogenase and antitrypsin tests give variable results and are not considered to be reliable. Two of the difficulties encountered are that the efficiency of the tests is not so good in the colostral period, and that halves adjoining affected halves give higher than normal results.

Treatment and control
Treatment and control of mastitis techniques to be used in goat does can be adapted from those used for cattle, with the details of dry period and lactational techniques to be used in goat does can be adapted from those used for cattle, with the details of dry period and lactational treatments supplied by a laboratory culture. If the cow dose rate is used, retention of the antibiotic in the udder will be prolonged and the withholding period will need to be increased. Antibiotic residue tests for screening bovine milk adequately identify goat's milk that is free of antibiotic residues. Vaccination against S. agalactiae in goats causes a rise
in serum antibodies that may provide a degree of immunity. Intravenous flunixin meglumine (two doses at 2.2 mg/kg BW 8 hours) was a more effective antipyretic agent in goats with experimentally induced coliform mastitis than intravenous dexamethasone (0.44 mg/kg BW once).19

Mastitis of mares
Mastitis in mares is rare. Corynebacterium pseudotuberculosis, Pseudomonas aeruginosa, Streptococcus zooepidemicus, Streptococcus equi, Streptococcus pyogenes, Staphylococcus aureus, Escherichia coli, Klebsiella spp., and Neisseria spp. are all recorded.1,2 Beta-hemolytic streptococci have been found in the milk of many normal, just-foaled mares.3

Clinical cases occur at any time during the lactation and many occur in non-lactating mares. Many mares with typical signs of severe swelling and soreness of the udder, but without abnormal milk, are first observed when a sick foal has not sucked for 24 hours. In streptococcal mastitis there may be severe local pain and moderate systemic signs. In most cases both halves are affected. Gangrenous mastitis similar to that in cows occurs occasionally.

Severe cases, sometimes accompanied by fever, depression, and anorexia, show swelling, pain, and heat in the affected half, ventral edema and clots in the milk; the mare is lame in the leg on the affected side. Gangrene and sloughing of the ventral floor of a gland may occur.

Because of the high frequency of Gram-negative bacteria as causative agents in mares, treatment should include a broad-spectrum antibiotic in an intramammary infusion plus intensive parenteral antibacterial treatment. Trimethoprim-sulfonamide preparations are generally satisfactory. Hot packs and frequent milk- ing are also recommended.

SPECIAL MEDICINE
Diseases associated with bacteria – I

Introduction to infectious disease

The infectious diseases are of major importance in agricultural animals. Accordingly, the bacterial, viral, fungal, protozoal and parasitic diseases account for a major portion of this book. The infectious diseases are capable of affecting many animals in a short period of time and the case fatality rate in some diseases can be very high and the economic losses may be very large. Certain infectious diseases, especially the viral diseases, are endemic in some countries and pose a threat to other countries considered to be free of them. The veterinary profession has made a major contribution in developing reliable diagnostic techniques and effective control procedures for many of these diseases. Some of the infectious diseases assume major importance because they are directly transmissible to humans.

REPORTABLE DISEASES (OIE LISTINGS)

Several infectious diseases of livestock have the potential for serious and rapid spread, implications for international trade and/or risk for significant zoonotic disease. Because of the nature of these diseases and the risk to regional or national animal health, their control is beyond the capability of the individual practitioner and requires the intervention of state and possibly national veterinary personnel and organizations. In most countries, diseases of this nature are listed as reportable diseases or notifiable diseases and these must be reported (notified) to the state or national veterinary authority immediately they are diagnosed.

A world organization for animal health, called the Office International des Epizooties (OIE), has been in existence for many years and its major objectives have been the collection, analysis, and dissemination of scientific veterinary information on animal diseases of significant veterinary importance. Member countries have traditionally reported to the OIE, on a regular basis, the occurrence, or absence, of these diseases in their respective countries. The purpose has been to ensure transparency in the global animal disease and zoonotic disease situation, and to provide expertise and encourage international solidarity in the control of animal diseases.

The OIE has established a Terrrestrial Animal Health Code (Terrestrial Code) where the majority of the reportable diseases are specifically detailed, including their clinical presentations, distribution amongst member countries and methods for diagnosis.\textsuperscript{1} The purpose of the Terrestrial Code is to assure the safety of international trade in terrestrial animals and their products by detailing the health measures to be used by the veterinary authorities of importing and exporting countries. The purpose is to avoid the transfer of agents pathogenic for animals or humans while also avoiding unjustified sanitary barriers. It constitutes a reference within the World Trade Organization (WTO) Agreement on the Application of Sanitary and Phytosanitary Measures (SPS Agreement) as an international standard for animal health and zoonoses.\textsuperscript{2,3} Traditionally, the OIE has classified animal diseases in two lists.

List A diseases (Box 16.1). These are transmissible diseases that have the potential for very serious and rapid spread, irrespective of national borders, that are of serious socioeconomic or public health consequence and that are of major importance in the international trade of animals and animal products. The presence of a list A disease in a country may limit or prevent its international trade of animals and animal products. In most countries the control and regulation of list A diseases are under the control of the federal veterinary authorities. Private practitioners have the responsibility to immediately report the occurrence, or
occurrence of certain listed diseases in a capacity for significant spread within national spread, but other criteria include convenience for the administration and recognition that many of the recent emerging, or re-emerging, diseases of animal origin have zoonotic potential. The overriding criterion for inclusion of a disease in the OIE single list remains its potential for international spread, but other criteria include a capacity for significant spread within naive populations and zoonotic potential. There has been agreement that the occurrence of certain listed diseases in a country does not necessarily preclude trade by that country in animal products. One of the reasons is that the disease may be absent from certain regions of the country that have geographical or ecological suspicion of their occurrence, to state or federal regulatory authorities.

List B diseases (Box 16.2). These are transmissible diseases that are considered to be of socioeconomic and/or public health importance within countries and that are significant in the international trade of animals and animal products. The control of these diseases varies between countries and between diseases in this list, but most countries require that they be reported to state or federal authorities if they are diagnosed.

2005 single list
In 2005 the OIE reorganized the diseases in the Terrestrial Code to a single list (Box 16.3). In part, this was done in response to concerns that the administration and listings of diseases had led to unfair trade restrictions on certain countries. The new listing is accompanied by the expectation of better international cooperation in the detection and control of animal disease, and support for developing countries in the diagnosis and control of these diseases is proposed. There is also the recognition that many of the recent emerging, or re-emerging, diseases of animal origin have zoonotic potential. The overriding criterion for inclusion of a disease in the OIE single list remains its potential for international spread, but other criteria include a capacity for significant spread within naive populations and zoonotic potential. There has been agreement that the occurrence of certain listed diseases in a country does not necessarily preclude trade by that country in animal products. One of the reasons is that the disease may be absent from certain regions of the country that have geographical or ecological

Box 16.1 List A diseases for cattle, swine, horses, sheep and goats
Transmissible diseases that have the potential for very serious and rapid spread, irrespective of national borders, that are of serious socioeconomic or public health consequence and that are of major importance in the international trade of animals and animal products
- Foot and mouth disease
- Swine vesicular disease
- Vesicular stomatitis
- Classical swine fever
- African swine fever
- Peste des petits ruminants
- Lumpy skin disease
- Bluetongue
- African horse sickness
- Rinderpest
- Contagious bovine pleuropneumonia
- Rift Valley fever
- Sheeppox and goat pox

Box 16.2 List B diseases for cattle, swine, horses, sheep and goats
Transmissible diseases that are considered to be of socioeconomic and/or public health importance within countries and that are significant in the international trade of animals and animal products

Affecting more than one animal species
- Anthrax
- Aujeszky’s disease
- Echinococcosis/hydatidosis
- Heartwater
- Leptospirosis
- Q fever
- Rabies
- Paratuberculosis
- New world screwworm (Cochliomyia hominivorax)
- Old world screwworm (Chrysomya bezziana)
- Paratuberculosis (Johnes’ disease)
- Q fever
- Rabies
- Trichinellosis

Cattle
- Bovine anaplasmosis
- Bovine babesiosis
- Bovine brucellosis
- Bovine cysteriosis
- Bovine genital campylobacteriosis
- Bovine spongiform encephalopathy
- Bovine tuberculosis
- Dermatophiosis
- Enzootic bovine leukosis
- Hemorrhagic septicaemia
- Infectious bovine rhinotracheitis/infectious postular vulvovaginitis
- Malignant catarrhal fever
- Theileriosis
- Trichomonosis
- Trypanosomosis (tsetse-transmitted)

Swine
- Atrophic rhinitis of swine
- Enterovirus encephalomyelitis
- Porcine brucellosis
- Porcine cysteriosis
- Porcine reproductive and respiratory syndrome
- Transmissible gastroenteritis

Horses
- Contagious equine metritis
- Dourine
- Epizootic lymphangitis
- Equine encephalomyelitis (Eastern and Western)
- Equine infectious anemia
- Equine influenza
- Equine proplasmosis
- Equine rhinopneumonitis
- Equine viral arteritis
- Glanders
- Horse mange
- Horse pox
- Japanese encephalitis
- Sural (Trypanosoma evansi)
- Venezuelan equine encephalomyelitis

Sheep and goats
- Caprine and ovine brucellosis (excluding Brucella ovis)
- Caprine arthritis/encephalitis
- Contagious agalactia
- Contagious caprine pleuropneumonia
- Enzootic abortion of ewes (ovine chlamydiosis)
- Maedi-visna
- Nairobi sheep disease
- Ovine epidemicynitis (B. ovis)
- Ovine pulmonary adenomatosis
- Salmonellosis (Salmonella abortus-ovis)
- Scrapie

Box 16.3 2005 single list of diseases notifiable to the Office International des Epizooties

Affecting more than one animal species
- Anthrax
- Aujeszky’s disease
- Echinococcosis/hydatidosis
- Heartwater
- Leptospirosis
- Q fever
- Rabies
- Paratuberculosis
- New world screwworm (Cochliomyia hominivorax)
- Old world screwworm (Chrysomya bezziana)
- Trichinellosis
- Foot and mouth disease
- Vesicular stomatitis
- Lumpy skin disease

- African horse sickness
Box 16.3 (Cont'd) 2005 single list of diseases notifiable to the Office International des Epizooties

Sheep and goats
- Ovine epididymitis (Brucella ovis)
- Caprine and ovine brucellosis (excluding B. ovis)
- Caprine arthritis/jersephalitis
- Contagious agalactia
- Contagious caprine pleuropneumonia
- Enzootic abortion of ewes (ovine chlamydiosis)
- Ovine pulmonary adenomatosis
- Nairobii sheep disease
- Salmonellosis (Salmonella abortus-ovis)
- Scrapie
- Maedi-visna
- Peste des petits ruminants
- Sheep pox and goat pox

characteristics that would not support the disease – an example would be areas of a country that did or did not support the vectors for bluetongue. It is also recognized that management systems may allow freedom from disease and that consequently there could be trade from production systems using these management methods – an example would be the disease and security status in a high health swine unit compared to free-range pigs in the same area. There is also the recognition that many of the recent emerging, or re-emerging diseases of animal origin have zoonotic potential.

We have listed the old List A and List B categorizations of diseases as these categories are familiar to practicing veterinarians and we suspect that they will be referred to, as such, in the lifetime of this edition of this book. We further believe that there was some meaning for practicing veterinarians, in terms of disease significance and emergency response, in the old List A and List B categorization that is not evident in the new single listing, which, although it might be politically correct, has less impact for those who practice clinical veterinary medicine at the level of the farm. We have reservations concerning the new single listing and reservations about some of the diseases selected for listing. There are several examples, but three will suffice. We question how a disease such as leptospirosis, generically essentially a universal infection in farm animals, can be equated and placed in a single list with a disease such as foot and mouth disease. We question how African horse sickness, with its huge potential for spread outside Africa, can be compared with the ubiquitous, and usually clinically insignificant, equine rhinopneumonitis. We question the inclusion of a disease such as atrophic rhinitis in the swine list of diseases and the exclusion of a disease such as pleuropneumonia, but more importantly, we question why atrophic rhinitis should be equated in economic, or response, importance to African swine fever.

### DIAGNOSIS OF INFECTIOUS DISEASES

The clinical and laboratory diagnosis of the infectious diseases can be difficult. However, with the appropriate laboratory support and suitable samples, most of them can be diagnosed definitively. For each disease certain samples must be submitted to the laboratory for isolation or demonstration of the specific pathogen.

Clinical and epidemiological findings will usually result in a tentative diagnosis and a rule-out list of possible diagnoses. When herd or area population epidemics occur, a detailed examination of the epidemiological characteristics of the disease is often useful in helping to make a diagnosis and in advising on the best treatment and control procedures. Particular attention should be given to the epidemiological aspects of the history, for example:

- The **descriptive epidemiology** including the distribution in age or other groups
- The morbidity and case fatality and population mortality rates
- The seasonal incidence
- Relationship to other species
- Recent changes in management
- Vaccination history
- Nutritional history
- Disease in previous years
- Source of imported animals
- Known risk factors for the diseases under consideration
- The treatments used and the success rate.

The epidemiological behavior of the epidemic includes an examination of the manner of spread of disease between individuals and groups of animals, the age of animals affected, the length of the course of the disease and the estimated incubation period. It may be necessary to establish a prospective survey or surveillance studies on sentinel herds to monitor the spread of the disease. Field investigation may include the examination of nearby herds or other species, such as wildlife or humans, that may be sources of the infection.

When an infectious disease is suspected, **laboratory investigations** will aid in diagnosis and differential diagnosis. The veterinary literature contains a large number of reports of the development of antibody-detection or antigen-detection tests for individual animal diseases. Most of these have not been validated in a significant number of animals for sensitivity and specificity in disease detection, and most are not available commercially or available on line in diagnostic laboratories. Those that are on line vary between countries and between laboratories within countries. The practitioner should consult the appropriate diagnostic laboratories to determine the tests that are available and the laboratories’ definition of the sensitivity and specificity of the test to be used. The recommended techniques of investigation and the common differential diagnoses are given for each disease.

- Clinical, hematological, clinical chemistry and immunological examinations, as appropriate, should be done on as many clinically affected animals as possible. Similar examinations should be conducted on normal animals that have been in close contact with the affected animals. The detection of latent carriers among clinically normal animals may require special laboratory tests. Repeated visits and examinations may be necessary to determine the presence and rate of seroconversion in an affected herd as an indication of the rate and direction of spread
- Tissue samples from necropsies and from live animals (biopsies) and discharges, feces and urine should be submitted for isolation or demonstration of the suspected pathogen.

The responsibility of the veterinarian in the case of infectious diseases is to advise the owner of the **risks of spread** to other animals or populations and the need for treatment and/or control. In the case of notifiable diseases, the government regulatory authorities must be notified immediately. Every precaution must be taken to prevent the spread of the disease to nearby herds or other geographical areas. Veterinarians have the responsibility to advise the owner of zoonotic risk of the disease to the farm family and farm workers. Veterinarians also have a responsibility to alert their clients to the possibility that an infectious disease may be approaching geographically and to take the necessary precautions. The **control** of infectious diseases is dependent on a knowledge of the etiology and epidemiological characteristics of the disease. The basic principles of disease control are:

- Reduce the infection pressure
- Eliminate or minimize risk factors that can be influenced
- Increase the nonspecific immunity
- Increase the specific immunity.

Any one or a combination of the following may be effective for the control of a specific infectious disease:
Insure adequate colostral immunity in the newborn

Identify affected animals, isolate them from the normal animals and treat or dispose of them as indicated, or return them to the herd if they are considered to be safe

Prevent the introduction of infected animals into herds previously considered free of the disease. Quarantine all animals imported into a herd for a period of 30–60 days. Serological testing may be done on the imported animals

Determine the source of the infection and remove it if possible. Sources include infected animals, feed and water supplies, wildlife and contaminated environments

Control by the use of mass medication of feed and water supplies may be appropriate with some diseases

Clean and disinfect animal houses and grounds regularly – this is essential. When animals occupy a barn for prolonged periods (weeks or months) without a clean-out and disinfection, the buildup of infectious agents increases almost geometrically and the incidence of disease will increase correspondingly

Provide an optimal environment for housed animals. This includes adequate ventilation, the prevention of overcrowding and effective removal of manure

Establish primary breeding stock through the use of specific-pathogen-free animals obtained by hysterectomy or cesarean section and rearing them under controlled conditions; this program may be indicated for the control of diseases such as enzootic pneumonia of swine

Vaccinate susceptible animals against endemic diseases; this should be part of a regularly scheduled herd health program that includes vaccination of the pregnant dam for the enhancement of colostral immunity in the newborn

Avoid stress associated with long transportation, inclement weather and undernutrition

Base effective control of intestinal parasites on measures designed to prevent or limit contact between parasite and host. The strategies are to: a) prevent the build-up of dangerous numbers of larvae on pastures; and b) anticipate the periods during which large numbers of larvae are likely to occur and remove susceptible animals from heavily contaminated pastures before these periods. These aims can be achieved using three interrelated approaches: grazing management, the use of anthelmintics and dependence on the acquisition of immunity.

REFERENCES

Diseases associated with Streptococcus species

Mastitis associated with Streptococcus agalactiae, Streptococcus dysgalactiae, Streptococcus uberis, and Streptococcus zoonoepidemicus is dealt with in Chapter 15. Strangles in horses, neonatal streptococcal infections, disease associated with S. zoonoepidemicus in horses and streptococcal cervical abscesses of pigs are dealt with later in this section.

Other miscellaneous diseases in which streptococci appear to have etiological significance include septicemic infections of swine, sheep and calves, pneumonia in calves, meningoencephalitis and otitis media in feeder pigs, lymphangitis in foals and infectious dermatitis of piglets.

SEPTICEMIA

Acute streptococcal septicemia of adult sows and their litters occurs sporadically. The onset is sudden and death occurs in 12–48 hours. Clinically there is weakness, prostration, fever, dyspnea, dysentery and hematuria. At necropsy, petechial and ecchymotic hemorrhages are present throughout all organs. Animals that survive for several days show extensive edema and consolidation of the lungs. The infection spreads rapidly and the mortality rate may be very high unless the drug sensitivity of the organism, usually S. zoonoepidemicus or Streptococcus equisimilis, is determined and appropriate treatment instituted

Experimental inoculation of S. zoonoepidemicus into horses causes fever, depression, anorexia, abnormal lung sounds, joint inflammation accompanied by mild–severe lameness, emaciation and a leukocytosis.

Streptococcus pneumoniae is the apparent cause of septicemia with sudden death in calves

In ruminants of all ages Streptococcus suis, usually a pathogen in pigs, causes a bacteremia with localization in many organs, including lungs, joints, bones, and meninges

In sheep and goat flocks, septicemia due to S. zoonoepidemicus causes up to 90% mortality in lambs and kids. S. dysgalactiae is a common cause of polyarthritis in lambs.

ENTERITIS

Streptococcus (Enterococcus) durans has been isolated from a foal with enteritis and has caused mild enteritis and diarrhea in foals infected orally. This organism has also been isolated from outbreaks of diarrhea in neonatal pigs and disease has been produced in gnotobiotic piglets. Streptococcus entericus sp. nov. has been isolated from the intestine of a cow with enteritis but its causal significance is not known.

PNEUMONIA

A syndrome of pneumonia and fibrinous pleuritis and pericarditis is caused in lambs by S. zoonoepidemicus

Pneumonia in calves may be associated with S. pneumoniae, and unidentified streptococci are common invaders in viral pneumonia of calves. Infections in calves with S. pneumoniae may have public health significance; the isolation of identical strains of the organism from the lungs of calves dying of the disease and from the throats of their human attendants suggests that interspecies transmission may occur. Calves may be immunized either by the use of antiserum or through vaccination of their dams with a polyvalent aluminum hydroxide-adsorbed vaccine

S. pneumoniae is also associated with inflammatory disease of the lower respiratory tract of horses, sometimes in association with a virus and sometimes with S. zoonoepidemicus.

Streptococcal pneumonia can be a complication of systemic corticosteroid therapy in horses.

MENINGOENCEPHALITIS

Meningoencephalitis is a common complication of streptococcal septicaemia of the newborn but S. suis is a specific cause in pigs and is dealt with under that heading. Streptococcal meningitis is restricted to the neonate in all species except piglets with S. suis and rarely lambs where sporadic meningitis in 3–5-month-old lambs occurs. Streptococcal meningitis and brain abscess may be a rare complication in horses of sinsitus and rhinitis.

LYMPHANGITIS

An ulcerative lymphangitis, caused in many instances by S. zoonoepidemicus, has been observed in foals from 6 months to 2 years of age and may be confused with...
Dermatitis

Infectious dermatitis (contagious pustular dermatitis of pigs) is characterized by the formation of pustules on the face and neck, and to a lesser extent the trunk. Streptococci and staphylococci are present in the lesions and spread appears to occur through abrasions, especially in young pigs that fight and have not had their needle teeth removed. The disease may be confused with exudative dermatitis.

Arthritis in Lambs

In the UK, *S. dysgalactiae* is a significant cause of outbreaks of arthritis in lambs, especially during the first 3 weeks of life. It occurs more commonly in lambs that are lambed indoors. Affected lambs are lame in one or more legs and are often found recumbent. There is minimal joint swelling in the initial stage of the disease and for this reason differential diagnoses include nutritional myopathy, swayback and spinal abscess. Infection is present in any joint but most common in the tarsal and atlanto-occipital joints. Some die with systemic disease and myocarditis. Survivors may be chronically lame.

Genital Tract Infections

Streptococcal infections of the genital tract, including *S. zooepidemicus*, occur commonly, especially in mares, in which the disease is thought to be spread by coitus and is accompanied by a high incidence of abortion, sterility and neonatal infection in foals.

Foals from infected mares may be affected each year. Although streptococcal metritis occurs in sows, there appears to be no relationship between uterine infection and neonatal septicemia. Abortions in sows may be associated with infection with beta-hemolytic streptococci.

One of the important features of streptococcal diseases is their lack of susceptibility to control by vaccination. Vaccines against streptococci in horses, *S. suis* in pigs and cervical adenitis of pigs are available, but results with them are equivocal. When the vaccines are properly prepared and carefully and intelligently applied the results are good. However, it is apparent that the streptococci are not good antigens and that the vaccines made with them lack the ease of application and safety that one expects with, say, the clostridial vaccines.

STRANGLES (EQUINE DISTEMPER)

Etiology

*Streptococcus equi* subsp. *equi*

Epidemiology

Highly contagious disease that affects horses of all ages but is most common in young animals. Prolonged carrier state in asymptomatic animals

Clinical signs

Acute onset of fever, anorexia, depression, submandibular and pharyngeal lymphadenopathy with abscessation and rupture, and copious purulent nasal discharge. Metastatic infection in other organs.

Clinical pathology

Culture of *S. equi* from nasal and abscess discharge.

Polymerase chain reaction (PCR) of nasal, pharyngeal or guttural pouch swabs. High serum antibody titer to *S. equi*.

Lesions

Caseous lymphadenopathy with rhinitis and pharyngitis, pneumonia and metastatic infection in severe cases.

Diagnostic confirmation

Culture of *S. equi*.

Treatment

Systemic administration of penicillin. Local treatment of abscesses. Control isolation and quarantine of cases and new admissions to barns and stables. Detection of carrier status by PCR and/or culture of guttural pouch washings. Vaccination may reduce the case attack rate and severity of disease.

ETIOLOGY

*Streptococcus equi* subsp. *equi* is a Gram-positive coccobacillus that produces a beta-hemolysin, evident as a zone of clear hemolysis surrounding colonies growing on blood agar. There is evidence that *S. equi* is a biovar or genovar of *S. zooepidemicus*. *S. equi*, which is highly host-adapted to Equidae, demonstrates no serological variation, although genetic analysis demonstrates the existence of clones that vary geographically.

There is variation in virulence related to the amount of M protein and hyaluronic capsule produced.

An atypical milder form of the disease is associated with a capsule-deficient variant of *S. equi*.

EPIDEMIOLOGY

Occurrence

Strangles occurs in horses, donkeys, and mules worldwide. Outbreaks are seen relatively frequently on breeding farms and in polo and racing stables, when the infection is introduced by new arrivals that are often asymptomatic, and in horses taken to fairs and riding schools. An incidence of 35% over a 3-year period is reported for horse studs in Australia.

Strangles can affect horses of any age, although the morbidity rate is usually greater in younger horses such as foals and weanlings. Age-specific attack rates of strangles of 18% for brood mares, 48% for 1-year-old horses and 38% for foals during an outbreak on a breeding farm are reported, although higher morbidity rates (100%) can occur, especially in young horses. The risk of occurrence of an outbreak of strangles increases with the size of the group of horses: farms with 100 or more horses have a 26 times greater risk of experiencing an outbreak than farms with fewer than 15 horses.

The case-fatality rate without treatment is about 9%, but with adequate early treatment may be as low as 1–2%. Deaths are usually due to pneumonia.

Source of infection and transmission

*S. equi* is an obligate parasite of horses and all infections are attributable to transmission from infected horses, either directly or by fomites. Nasal and abscess discharge from infected animals that contaminates pasture, tack, stalls, feed and water troughs, grooming equipment, and hands and clothes of grooms and veterinarians is often the source of infection for susceptible horses. *S. equi* can survive in the environment for at least 2 months, and fomite transfer is important in transmission of infection. Direct transmission from infected animals to susceptible animals occurs through contact.

Approximately 10–40% of horses that recover from the clinical disease have persistent infection of *S. equi* in the pharynx and guttural pouches for many months and are an important source of infection.

Horses with clinically apparent disease, such as some cases of guttural pouch empyema, may shed the organism for over 3 years. The period of infectivity is important in terms of the length of quarantine that needs to be imposed on horses that have apparently recovered from the disease. Because shedding of *S. equi* may be intermittent, repeated culture of nasopharyngeal swabs or use of PCR examination of guttural pouch washings may be necessary to document the carrier status of individual horses. Endoscopic or radiographic examination of clinically inapparent shredders may demonstrate lesions in the guttural pouches, paranasal sinuses, or pharynx. However, some persistent carriers of *S. equi* do not have detectable abnormalities of the nasopharynx. The clinically inapparent nature of the infection makes detection of carriers problematic, especially...
when considering introduction of horses into a previously closed herd in which strangles is not endemic.

**Animal risk factors**

Strangles is more common in young or naive horses, although the disease can occur in horses of any age. Animals that have previously had the disease are less likely than naive animals to develop the disease on subsequent exposure. A proportion (approximately 25%) of horses that recover from the disease do not develop a protective immune response and are susceptible to reinfection and a second bout of strangles. Resistance to the disease is associated with the production of serum and mucosal IgG antibodies to the streptococcal M protein. The presence in the nasopharynx of antibodies to streptococcal M protein is thought to be important in conferring resistance to the disease. Serum IgG antibodies specific for the M protein, which is important in the antigenic activities of *S. equi*, are produced by most but not all horses during convalescence. Similarly, IgA and IgG against M protein are detectable on nasal and pharyngeal mucosa after *S. equi* infection but not after intramuscular administration of vaccines containing M protein. Serum bactericidal activity alone is not considered to be a good indicator of resistance to the disease, especially if it is induced by administration of a vaccine. Antibodies similar to those found in the nasopharynx after infection with *S. equi* are present in colostrum and milk of mares that have recovered from the disease, are passed to foals via the colostrum and are secreted into the foal's nasopharyngeal mucosa. These acquired antibodies are important in mediating the resistance of young foals to the disease.

Although strong immunity occurs immediately after an attack, this immunity wanes with time and a horse may suffer further disease if the organism is virulent.

**Importance**

Strangles is one of the most important diseases of horses in developed countries, accounting for up to 30% of reported infectious disease episodes. The disease is not endemic. After an attack, this immunity wanes with time and a horse may suffer further disease if the organism is virulent.

**Pathogenesis**

Virulence of *S. equi* is attributable to the presence of M proteins on the surface of the bacteria, a hyaluronic acid capsule and the production of a leukocidal toxin. M proteins are associated with *S. equi* adhesion to oral, nasal, and pharyngeal tissues, invasion of pharyngeal tonsils and associated lymphoid structures, and evasion of the innate host immune response. *S. equi* produces two M proteins — SeM and SzPSe. SeM is unique to *S. equi* and plays a dominant role in resistance of the organism to phagocytosis. Variations in structure of M protein are associated with decreased virulence. The M proteins interfere with the deposition of complement component 3b on the surface of the bacteria and bind fibrinogen, both of which reduce the susceptibility of the bacteria to phagocytosis by neutrophils. The antiphagocytic activity of *S. equi* reduces the efficacy of neutrophils in engulfing and destroying the bacteria.

The capsule of *S. equi* is associated with resistance to non-immune phagocytosis and pathogenicity. Strains of *S. equi* that do not produce a capsule do not induce disease, although they are able to infect guttural pouches and cause seroconversion in experimental studies. Following exposure of the oral and nasopharyngeal mucosal surfaces to *S. equi*, antibody is produced in the pharyngeal and tonsillar lymphoid tissues where they multiply rapidly. There is no evidence of colonization of mucosal surfaces and streptococci can be detected in pharyngeal tonsils within hours of exposure. The binding of *S. equi* to pharyngeal cells is caused by fibrinogen binding proteins associated with M protein. The resistance of *S. equi* to non-immune phagocytosis results in accumulation of large numbers of organisms surrounded by degenerating neutrophils. Release of streptolysin S and streptokinase may contribute to tissue damage by directly injuring cell membranes and indirectly through activation of plasminogen.

Bacteremia may occur. Migration of neutrophils into the lymph nodes causes swelling and abscission, with associated disruption of lymph drainage and development of edema in tissues drained by the affected nodes. Swelling of retropharyngeal lymph nodes may interfere with deglutition and respiration. Most abscesses eventually rupture and drain and the infection resolves with the development of an effective immune response. Nasal shedding of *S. equi* usually begins 4–7 days after infection, or 2 days after onset of fever, and persists for 2–3 weeks in most horses but up to years in exceptional horses. Cessation of shedding accompanies development of an effective serum and mucosal immune response.

Death is usually due to pneumonia caused by aspiration of infected material, although other causes of death include asphyxiation secondary to upper airway swelling and impairment of organ function by metastatic infection. Rare deaths also occur as a result of infective purpura hemorrhagica in horses infected with *S. equi*.

**Metastatic infection** of the heart valves, brain, eyes, joints, and tendon sheaths or other vital organs may occur and cause a chronic illness and eventual death. Metastatic infection may occur because of bacteremia extension of infection along chains of lymph nodes. Purpura hemorrhagica may occur as a sequel to *S. equi* infection and is associated with high serum antibody titers to SeM.

**Clinical Findings**

The disease manifests as an acute disease of varying severity, chronic infection of retropharyngeal lymph nodes and guttural pouches, and as chronic disease associated with metastatic infection of organs distant to the upper respiratory tract. The severity of the acute disease varies with the age and immune status of the animal, and size of the inoculum and duration of exposure to infection. The term strangles derives from the enlarged retropharyngeal lymph nodes and guttural pouches causing respiratory distress in severely affected equids.

**Acute Disease**

The acute disease is characterized by mucopurulent nasal discharge and abscessation of submandibular and retropharyngeal lymph nodes. After an incubation period of 1–3 weeks the disease develops suddenly with complete anorexia, depression, fever (39.5–40.5°C, 103–105°F), a serous nasal discharge, which rapidly becomes copious and purulent, and a severe pharyngitis and laryngitis. Rarely there is a mild conjunctivitis.

**Lymphadenopathy** becomes apparent as the submandibular lymph nodes enlarge and palpation elicits a painful response. The pharyngitis may be so severe that the animal is unable to swallow and there is a soft, moist cough. The head may be extended.

The febrile reaction commonly subsides in 2–3 days but returns as the characteristic abscesses develop in the lymph nodes of the throat region. The affected nodes become hot, swollen, and painful. **Swelling of the retropharyngeal lymph nodes** may cause obstruction of the oro- and nasopharynx with subsequent respiratory distress and dysphagia. Death by asphyxiation may occur at this time in severe cases. Obvious swelling of the nodes may take 3–4 days to develop: the glands begin to exude serum through the overlying skin at about 10 days and rupture to discharge thick, cream-yellow pus soon afterwards. Average cases run a course of 3 weeks, severe cases may last as long as 3 months.

Retropharyngeal abscesses may rupture into the guttural pouches, resulting in...
guttural pouch empyema and ultimately in prolonged infection and formation of chondroids. Retropharyngeal lymph node abscession may not be apparent on external evaluation and can often only be detected by radiographic or endoscopic examination of the pharynx. Infection of retropharyngeal lymph nodes and guttural pouches is important in persistent infection and carrier status of some horses.

If the infection is particularly severe, many other lymph nodes, including the pharyngeal, submaxillary, parotid and retobulbar nodes, may abscess at the same time. Local abscesses may also occur at any point on the body surface, particularly on the face and limbs, and the infection may spread to local lymphatic vessels causing obstructive edema. This occurs most frequently in the lower limbs, where edema may cause severe swelling. Abscess formation in other organs probably occurs at this time.

An atypical form of the disease may occur and is characterized by widespread subclinical infection and a mild disease. Affected horses have a transient fever for 24–48 hours and a profuse nasal discharge, and are anorexic. A moderate enlargement of the mandibular lymph nodes occurs in only about one-half of the affected horses.

Strangles in burros is a slowly developing debilitating disease. At postmortem examination the characteristic lesions consist of caseation and calcification of abdominal lymph nodes.

Complications
Complications occur in about 20% of cases. The most common fatal complication is the development of supplicative necrotic bronchopneumonia, which probably occurs secondary to the aspiration of pus from ruptured abscesses in the upper airway, or metastatic infection of the lungs.

Extension of the infection into the guttural pouches, usually as a result of rupture of retropharyngeal lymph nodes into the medial compartment, causes empyema, which may lead to the formation of crescent of inspissated pus (chondroids). Involvement of the guttural pouches is evident clinically as distension and, after resolution of other signs, unilateral or bilateral nasal discharge. Guttural pouches of affected horses should be examined endoscopically for evidence of retropharyngeal abscessation or guttural pouch empyema or chondroid formation.

Retropharyngeal lymphadenopathy may impair the function of the recurrent laryngeal nerves, with subsequent unilateral or bilateral laryngeal paresis and consequent respiratory distress.

Metastatic infection (‘bizarre strangles’) results in the formation of abscesses in any organ or body site but most commonly in the lungs, mesenteric lymph nodes, liver, spleen, kidneys, and brain. Clinical signs depend on the organ affected and the severity of the infection, but intermittent fever, chronic weight loss and sudden death due to rupture of abscesses into a body cavity are common manifestations of metastatic infection. Rectal examination or percutaneous ultrasonographic examination may reveal intra-abdominal abscesses in some horses with metastatic abscesses in the abdomen. Peritoneal fluid from these horses is often abnormal.

Metastatic infections may occur in the central nervous system. Extension of infection to the meninges results in suppurative meningitis characterized clinically by excitation, hyperesthesia, rigidity of the neck, and terminal paralysis. Abscesses in the brain cause a variety of clinical signs, depending on location of the abscesses, including severe depression, head pressing, abnormal gait, circling, and seizures.

Metastatic infections of the ocular and extracranial structures, heart valves and myocardium, joints, bones, tendon sheaths, and veins may occur.

Purpura hemorrhagica can occur as a sequela to S. equi infection. Two myopathic syndromes occur with S. equi infection in horses. Muscle infarction, which may be extensive, is assumed to result from immune-mediated vasculitis associated with purpura hemorrhagica.

Often the muscle lesions in these horses are associated with other lesions consistent with severe purpura hemorrhagica, including infarctions in the gastrointestinal tract, skin and lungs. Rhabdomyolysis and subsequent muscle atrophy results in signs of muscle disease, including stilted gait and elevated serum activity of creatine kinase and other muscle-derived enzymes, and is assumed to be due to cross-reactivity of anti-SeM antibodies with myosin.

Myocarditis and glomerulonephritis have been suggested as sequelae to S. equi infection but have not been conclusively demonstrated to occur.

CLINICAL PATHOLOGY
Hematological abnormalities during the acute phase of the disease include leukocytosis with a neutrophilia reaching a peak as the lymph nodes abscess. Hyperfibrinogenemia is characteristic of both the acute and chronic disease. Hematological and biochemical abnormalities associated with metastatic infection depend on the site of the infection and its severity. Leukocytosis with a hyperproteinemia attributable to a polyvalent gammaglobulinemia is characteristic of metastatic and chronic abscessation. Hypoalbuminemia may be present. Serum biochemical profile may reveal evidence of specific organ dysfunction. There may or may not be an anemia, which may be due to the hemolytic effect of streptolysin O, immunemediated hemolysis, or anemia of chronic disease.

A commercial test that measures the serum IgG antibody titer to SeM has been developed and has been used to determine response to vaccination, suitability for vaccination and presence of metastatic infection. The test is not useful in diagnosis of the acute disease. Serum antibody titers to SeM are very high (> 1:12 800) in horses with metastatic infection or purpura hemorrhagica.

PCR testing is useful to detect shedding of S. equi DNA. The test is reported to be more specific than culture for detection of S. equi shedding. The PCR does not differentiate between live and dead S. equi and false-negative results occur in the presence of large numbers of S. equi. PCR testing should be considered an adjunct to routine culture for detection of S. equi.

Culture of nasal, pharyngeal, guttural pouch, or abscess discharge will usually yield S. equi in horses with active disease or in carriers. Abscesses may rapidly become contaminated with S. zooepidemicus, which may impede isolation of S. equi.

NECROPSY FINDINGS
In the rare fatalities that occur, necropsy examination usually reveals suppuration in internal organs, especially the liver, spleen, lungs, pleura, and peritoneum. When the last is involved, it is usually as a result of extension from abscesses in the mesenteric lymph nodes. The microscopic changes of abscessation and supplicative lymphadenitis are uncomplicated. The widespread ecchymotic hemorrhages of purpura hemorrhagica are not specific to this infection, but S. equi should always be investigated as a potential cause of such lesions.

Samples for confirmation of diagnosis
Bacteriology — swab of abscess wall, enlarged lymph node (CULT).

DIAGNOSTIC CONFIRMATION
Confirmation of strangles depends on the isolation of S. equi from nasopharyngeal swabs and discharges from abscesses. Shedding of S. equi in nasal discharges begins 1–4 days after the onset of fever, and ruptured abscesses often become contaminated with Streptococcus zooepidemicus and S. equisimilis.

TREATMENT
The specific treatment of choice for S. equi infection of horses is penicillin, either as...
DIFFERENTIAL DIAGNOSIS

See Table 16.1 for a list of differential diagnoses of infectious upper respiratory tract disease of horses. Pneumonia should be differentiated from pleuropneumonia associated with transport or other stress. Chronic weight loss due to metastatic infection should be differentiated from equine infectious anemia, parasitism, inadequate nutrition and neoplasia, especially gastric squamous cell carcinoma, alimentary lymphosarcoma and granulomatous enteritis.

Procaine penicillin G (22,000 IU/kg intramuscularly every 12 h) or potassium or sodium penicillin G (22,000 IU/kg intravenously every 6 h). Tetracycline (6.6 mg/kg intravenously every 12–24 h) and sulfonamide–trimethoprim combinations (15–30 mg/kg orally or intravenously every 12 h) may be efficacious but should only be used if penicillin cannot be administered. Aminoglycosides, such as gentamicin or amikacin, and the fluoroquinolones are not effective.

There is considerable debate about the treatment of horses with strangles. Folklore and anecdotal reports suggest that antibiotic treatment of horses with strangles is contraindicated because it promotes the development of metastatic infection. There is no experimental or empirical evidence to support this contention and horses with strangles should be treated with therapeutic doses of an appropriate antibiotic, such as procaine penicillin, for a period of time sufficient to effect a cure, as appropriate.

Treatment for *S. equi* infection depends on the stage of the disease.28

ELISA, enzyme-linked immunosorbent assay; PCR, polymerase chain reaction.
stable or yard. However, treated horses may not develop a protective immune response and consequently may be at risk of reinfection if exposed to *S. equi* after completion of the course of treatment, leading one authority to recommend that only severely affected animals be treated.\(^{26}\)

- Horses with submandibular lymph node abscessation but without other clinical abnormalities probably do not require antibiotic treatment. Such horses should be isolated and efforts made to aid maturation and rupture of affected lymph nodes.
- Systemic antibiotic therapy with penicillin is indicated in horses with **advanced signs of strangles**, including prolonged fever, depression, anorexia or dyspnea resulting from retropharyngeal lymphadenopathy. Retropharyngeal abscessation frequently responds to antimicrobial therapy, although surgical drainage may be required in some instances.\(^{29}\)
- Horses with **metastatic infection** require systemic penicillin therapy in combination with specific therapy for the complication. Pulmonary and mesenteric abscesses are problematic because they are usually not amenable to surgical drainage, and prolonged antimicrobial therapy is required to effect a cure.
- **Guttural pouch empyema** requires either surgical drainage or repeated flushing of the affected pouch through the pharyngeal openings.\(^{31}\)
  - Removal of pus and inspissated material in the guttural pouches can be achieved under endoscopic guidance. Alternatively, rigid or flexible indwelling catheters can be inserted for repeated flushing of the pouches with sterile isotonic electrolyte solutions (such as 0.9% NaCl) and topical medications.
  - Substances and solutions that are irritating or injurious to mucus membranes, such as iodine, hydrogen peroxide and similar irritant compounds, should not be infused into the guttural pouches. Combined topical and systemic administration of potassium benzyl penicillin may be beneficial.\(^{30}\)
  - Chondroid can often be removed using wire snares. Horses with metastatic or guttural pouch infections should be isolated.
  - **Treatment of purpura hemorrhagica** is dealt with elsewhere.
  - Management of horses that have been **exposed to** horses with strangles is controversial. Some authorities recommend treatment of such in-contact horses with penicillin until affected horses are isolated and no longer are a source of infection. However, close examination of exposed animals, including monitoring rectal temperature, and treatment of horses at the first sign of illness is probably a more reasonable approach.

### Ancillary treatment

Consists of administration of nonsteroidal anti-inflammatory drugs (NSAIDs) to reduce swelling and provide pain relief, application of hot poultices to encourage rupture of abscesses, provision of intravenous hydration in animals unable to drink, and wound care, including cleaning of ruptured abscesses and application of petroleum ointment to surrounding skin to prevent scalding. Horses with severe upper airway obstruction may require placement of a short-term tracheotomy.

### CONTROL

The principles of control measures include the prevention of transmission of *S. equi* from infected horses (cases or carriers) to susceptible animals and enhancement of resistance to infection and disease.

### Prevention of transmission

Preventing introduction of strangles to herds free of the disease is difficult, especially when there is frequent movement of horses in and out of the herd. Close attention should be paid to the health of horses introduced to herds free of the disease and, although this is an imperfect safeguard, the owner or manager of horses to be introduced to a herd should be questioned about the likelihood of exposure of the horse to strangles. Ideally, horses should be isolated for 3 weeks before introduction to a herd that is free of the disease and should have washings of the guttural pouches performed on three occasions at weekly intervals. The washings should be examined by culture and PCR for the presence of *S. equi*. Clearly, this requirement, while ideal, is demanding of time, space and labor, is expensive and would be difficult to implement as a routine practice.

Methods to control transmission of *S. equi* on affected premises are detailed in Table 16.2.\(^{19}\)

Table 16.2. Aim and Method of Prevention of Transmission of *S. equi* on Affected Premises

PCR, polymerase chain reaction.

The majority of horses develop solid immunity to strangles after recovery from the spontaneous disease. This immunity lasts for up to 5 years in approximately three-quarters of recovered horses. Maximum resistance to disease probably requires both systemic and mucosal immunity to a variety of S. equi factors including, but not limited to, M protein.19,32

Enhanced resistance
The majority of horses develop solid immunity to strangles after recovery from the spontaneous disease. This immunity lasts for up to 5 years in approximately three-quarters of recovered horses. Maximum resistance to disease probably requires both systemic and mucosal immunity to a variety of S. equi factors including, but not limited to, M protein.19,32

The efficacy of vaccination of adult horses with S. equi bacterins or M protein extracts of S. equi administered intramuscularly is controversial. Administration of M protein vaccines elicits an increase in the concentration of serum opsonizing antibodies but does not confer a high degree of resistance to natural exposure.3 Anecdotal and case reports suggest that vaccination is not effective. However, in a controlled field trial, vaccination with an M protein commercial vaccine three times at 2-week intervals reduced the clinical attack rate by 50% in a population of young horses in which the disease was endemic.33 Horses vaccinated only once were not protected against strangles.33 This result suggests that, in the face of an outbreak, vaccination may reduce the number of horses that develop strangles but will not prevent strangles in all vaccinated horses. A common vaccination protocol involves the administration of an M protein vaccine intramuscularly for an initial course of three injections at 2-week intervals, with further administration of the vaccine every 6 months in animals at increased risk of contracting the disease.34 On breeding farms, vaccination of mares during the last 4–6 weeks of gestation and of the foals at 2–3 months of age may reduce the incidence of the disease.35

The vaccines are administered by the intramuscular route and frequently cause swelling and pain at the injection site.34 Injection site reactions are usually less severe with the M protein vaccines. Injection into the cervical muscles may cause the horse to be unable to lower its head to eat or drink for several days – injection into the pectoral muscles is preferred for this reason. There are reports of purpura hemorrhagica, the onset of which was temporally associated with administration of a S. equi vaccine. Owners should be clearly warned of the limited efficacy and potential side-effects of vaccination.

Foals that receive adequate high-quality colostrum from exposed or vaccinated mares have serum and nasopharyngeal mucosal immunoglobulins (IgGb) that provide them with resistance to S. equi infection.6 This passive immunity wanes at approximately 4 months of age. Vaccination of brood mares 1 month before foaling increases colostral IgG antibodies to M protein, and presumably serum and mucosal immunoglobulin concentrations in their foals,3 but the efficacy of this approach in preventing strangles in foals is not reported.

An intranasal vaccine of an avirulent live strain of Streptococcus equi has recently been developed and appears useful. The vaccine is composed of a live variant (strain 707-27) that does not possess a capsule and is therefore avirulent when administered intranasally. Anecdotal reports suggest that recent manipulation of the genome by deletion of genes HsaA and HsaB, associated with formation of the capsule, has increased the genetic stability of the vaccine strain.36 The live attenuated vaccine should only be administered intranasally to healthy horses. The efficacy of the vaccine in field situations, safety in the face of an outbreak and in pregnant mares, incidence of adverse effects and risk of reversion to virulence have not been reported. It should not be used in potentially exposed horses during an outbreak of the disease. Intramuscular injection of the vaccine results in the formation of abscesses. The vaccine should not be administered to horses concurrently with intramuscular administration of other vaccines because of the risk of contamination of needles and syringes with S. equi vaccine strain and subsequent development of abscesses at injection sites.

Vaccination by submucosal injection of a modified live vaccine is reported to provide short-lived (90-day) immunity to disease.37 The commercial form of the vaccine is administered into the submucosal tissues of the upper lip and is recommended for use in horses at moderate to high risk of developing strangles.38 At present there is no evidence of reversion of the vaccine strain to virulence, and horses developing strangles subsequent to vaccination have all been infected with virulent strains of S. equi, apparently before development of immunity as a result of vaccination.38

REVIEW LITERATURE

REFERENCES
STREPTOCOCCUS ZOEOEPIDEMICUS INFECTION

Streptococcus equi var. zooepidemicus (S. zooepidemicus) is one of the bacteria most commonly isolated from the upper respiratory tract of clinically normal horses. It almost always harbor a number of antigenic types of S. zooepidemicus in their tonsils, and this may be the source of opportunistic infections of other body systems, including the lungs. Pneumonia in an individual horse is usually associated with a single strain of S. zooepidemicus, based on variants of the M-protein-like compound SzP. However, there are a large number of SzP phenotypes and it does not appear to be an important determinant of invasiveness or epizootic capability. S. zooepidemicus is also frequently isolated from horses with pleuropneumonia, endometritis, neonatal septicemia, abortion, and mastitis, suggesting a role for this organism in the pathogenesis of these diseases. S. zooepidemicus is likely important in the development of respiratory disease in foals and adult horses. S. zooepidemicus was isolated from 88% of foals with clinical evidence of lower respiratory tract disease, and isolation of the organism was associated with an increased proportion of neutrophils in bronchoalveolar lavage fluid, suggesting a causal role for this organism. Similarly, the number of S. zooepidemicus isolated from tracheal aspirates of adult horses is directly proportional to the number of neutrophils in the aspirate and the probability that they have a cough. The association of S. zooepidemicus and inflammatory airway disease in race horses is independent of previous viral infection, suggesting a role for S. zooepidemicus as a primary pathogen. Presence and number of colony forming units (cfu) of S. zooepidemicus in tracheal aspirates of horses is significantly associated with the risk of the horse having inflammatory airway disease. Adult horses dying of pneumonia associated with transportation often yield S. zooepidemicus on culture of lung lesions and the disease can be reproduced experimentally. These results clearly demonstrate a role for S. zooepidemicus in the pathogenesis of respiratory disease of horses. However, it is unclear whether S. zooepidemicus is a primary cause of disease, a secondary contaminant or an invader of Airways compromised by viral infection or other agents.

Clinical signs of S. zooepidemicus infection of the lower respiratory tract of foals and horses include coughing, mild fever, mucopurulent nasal discharge, and increased respiratory rate. Endoscopic examination of the trachea and bronchi reveals erythema and presence of mucopurulent exudate. Tracheal aspirates or broncho­alveolar lavage fluid of affected horses or foals have an increased (>10%) proportion of neutrophils. S. zooepidemicus is a frequent isolate from the cornea of horses with ulcerative keratitis.

Treatment consists of the administration of antimicrobials including penicillin (procaine penicillin, 20,000 IU/kg every 12 h) or the combination of a sulfonamide and trimethoprim (15–30 mg/kg orally every 12 h). Control consists of isolation to prevent spread of infectious respiratory disease and vaccination to prevent viral respiratory disease.

NEONATAL STREPTOCOCCAL INFECTION

Etiology Various Streptococcus spp. 
Epidemiology Neonatal foals, calves, lambs, piglets

Signs Acute painful swelling of joints, lameness, fever. Signs of meningitis, septicemia, purulent meningitis and septicemia. Sudden death

Clinical pathology Culture organism from joint fluid

Necropsy findings Fibrinopurulent synovitis, purulent meningitis and septicemia.

Diagnostic confirmation Recovery of organism from joint fluid

Differential diagnosis Other infectious causes of arthritis, meningo­occultation and omphalophlebitis.

Treatment Antimicrobials, usually penicillin

Control See ‘Principles of control and prevention of infectious diseases of newborn farm animals’ in Chapter 3.

Diseases associated with Streptococcus species

ETIOLOGY

Streptococci are an important cause of septicaemia, polyarthritis, meningitis, polyserositis, endocarditis, and unexpected death in the neonates of all farm animal species. Meningitis associated with streptococcal infection is restricted to the neonate in all species except piglets, where outbreaks can occur in pigs after weaning, and lambs infected with S. suis, where meningitis can occur as a sporadic disease at 3–5 months of age. Historically, there are reports of isolates of most of the Lancefield groups of beta-haemolytic streptococci, of non-beta-haemolytic streptococci and of viridans group streptococci from neonatal disease in farm animals. Commensal skin streptococci can occasionally cause disease in presumably immunocompromised neonates. However, the majority of neonatal disease is associated with a limited number of streptococcal species, although there can be geographical variation in their relative prevalence within animal species.

In foals, S. equi (S. equi subsp. equi) and S. zooepidemicus (S. equi subsp. zooepidemicus) are the most common streptococcal species recovered from septicaemic disease and polyarthritis and are also a cause of placental arthritis and abortion in mares. In calves, S. dysgalactiae subsp. equisimilis is a less common isolate. S. suis and S. equisimilis are the most common species incriminated in piglets. S. suis is especially important and is presented separately in the next section. Other Lancefield groups have been associated with sporadic disease. In calves, S. dysgalactiae and S. uberis are the common streptococcal isolates from synovial fluid of neonatal calves with arthritis. S. dysgalactiae is also reported to be the most common cause of outbreaks of arthritis in neonatal lambs in Great Britain. Streptococci can also contribute to purulent infections at local sites, such as navel ill of all species or otitis media in neonatal calves.

EPIDEMIOLOGY

Occurrence and prevalence

The importance and relative prevalence of streptococcal infections in neonatal disease varies among countries and with surveys. Streptococci are a common cause of postnatal infections of foals, representing 50% of such cases in some surveys but with a lower prevalence in others. Up to 20% of abortions in mares are due to placentalitis from streptococcal infection. Streptococcal septicaemia due to beta-haemolytic streptococci may occur in foals under 5 days of age that have been stressed and have failure of transfer of passive immunity.

In calves, neonatal infections with streptococci are usually sporadic and less
common than infections with Gram-negative bacteria and may be predisposed by failure of transfer of passive immunity. In lambs, *S. dysgalactiae* is associated with outbreaks with high morbidity and in Great Britain is reported to be the cause of over 70% of cases of polyarthritis in lambs during their first 3 weeks of life. Despite the high attack rate in these outbreaks, it is rare for more than one of twins or triplets to have disease. Streptococcal arthritis associated with *S. suis* infection in piglets is a common disease and is covered in a separate section.

**Source of infection**
The source of the infection is usually the environment, which may be contaminated by uterine discharges from infected dams or by discharges from lesions in other animals. *S. dysgalactiae* is reported to survive for up to a year on clean straw, as opposed to wood shavings, which do not support the persistence of the organism.

The portal of infection in most instances appears to be the umbilicus, and continued patency of the urachus is thought to be a contributing factor in that it delays healing of the navel. In piglets there can be high rates of infection associated with infection entering through skin abrasions such as carpal necrosis resulting from abrasive floors or facial lesions following fighting. Contaminated knives at castration and tail docking, or contaminated ear taggers, can result in infection and disease. Other mechanical vectors include the screwworm fly (*Cochliomyia americana*).

The organism can be isolated from the nasopharynx of the sow, and direct infection from the sow to the piglet is suggested by some epidemiological data.

**Economic importance**
Affected foals and other species may die or be worthless as working animals because of permanent injury to joints. There is also loss due to condemnation at slaughter.

**Zoonotic implications**
*S. zooepidemicus* is associated with human infections, particularly nephritis, and many human infections can be traced back to the consumption of contaminated animal food products. Some strains of *S. equisimilis* can also infect humans.

**PATHOGENESIS**
The infection spreads from the portal of entry to produce a bacteremia that is not detectable clinically. The period of bacteremia is variable but it may last several days in piglets. A terminal acute fatal septicemia is the common outcome in animals under 1 week of age but in older animals suppurative localization in various organs is more common. Arthritis is the most common manifestation, with synovitis and invasion of medullary bone of the epiphysis with microabscessation and ischemic necrosis of bone. Other manifestations of infection include ophthalmitis in foals and calves, meningitis and endocarditis in piglets, meningitis in calves, and endocarditis and sudden death in lambs. Streptococcal endocarditis can be produced by the intravascular inoculation of group *L. Streptococcus*. Lesions are well established within 5 days, the left heart is most commonly affected, and myocardial and renal infarction occur.

**CLINICAL FINDINGS**

**Foals**
Foals do not usually show signs until 2–3 weeks of age. The initial sign is usually a painful swelling of the navel and surrounding abdominal wall, often in the form of a flat plaque, which may be 15–20 cm in diameter. A discharge of pus may or may not be present and a patent urachus is a frequent accompaniment. A systemic reaction occurs but this is often mild, with the temperature remaining at about 39.5°C (103°F). Lameness becomes apparent and is accompanied by obvious swelling and tenderness in one or more of the joints. The hock, stifle, and knee joints are most commonly affected but in severe cases the distal joints are involved and there is occasionally extension to tendon sheaths. Lameness may be so severe that the foal lies down most of the time, sucks rarely and becomes extremely emaciated. There may be hypopyon in one or both eyes.

Recovery occurs if treatment is begun in the early stages. When joint involvement is severe, particularly if the abscesses have ruptured, the animal may have to be destroyed because of the resulting ankylosis. Death from septicaemia may occur in the early stages of the disease.

**Piglets**
Arthritis and meningitis may occur alone or together and are most common in the 2–6-week age group. More commonly, several piglets within a litter are affected. The arthritis is identical with that described in foals above. With meningitis there is a systemic reaction comprising fever, anorexia and depression. The gait is stiff, the piglets standing on their toes, and there is swaying of the hindquarters. The ears are often retracted against the head. Blindness and gross muscular tremor develop, followed by inability to maintain balance, lateral recumbency, violent paddling and death. In many cases there is little clinical evidence of ophthalmobilitis. With endocarditis the young pigs are usually found comatosed or dead without premonitory signs having been observed.

**Lambs**
Lameness in one or more limbs of lambs up to 3 weeks of age is the common presenting sign of infection with *S. dysgalactiae* but approximately 25% of lambs can be initially recumbent. With this infection there is not major joint swelling in the early stages and myopathy or delayed swayback may be initial considerations. In contrast with outbreaks that occur following docking the incubation period is short, usually 2–3 days, and there is intense lameness, with swelling of one or more joints appearing in a day or two. Pus accumulates and the joint capsule often ruptures. Recovery usually occurs with little residual enlargement of the joints, although there may be occasional deaths due to toxemia.

**Calves**
These show polyarthritis, meningitis, ophthalmitis, and ophthalmobilitis. The ophthalmitis may appear very soon after birth. The arthritis is often chronic and causes little systemic illness. Calves with meningitis show hyperesthesia, rigidity, and fever.

**CLINICAL PATHOLOGY**

Pus from any source may be cultured to determine the organism present and its sensitivity to the drugs available. Bacteriological examination of the uterine discharges of the dam may be of value in determining the source of infection. The success rate with blood cultures is not very high but an attempt is worthwhile. The identification of the causative bacteria is important but the sensitivity of the organism may mean the difference between success and failure in treatment. The specific identity of the streptococcus should be determined.

**NECROPSY FINDINGS**

Suppuration at the navel and severe suppurative arthritis affecting one or more joints are usual. Abscesses may also be present in the liver, kidneys, spleen, and lungs. Friable tan masses of tissue are common on the heart valves of affected piglets and this valvular endocarditis may also be observed in other species. Peracute cases may die without suppurative lesions having had time to develop. Necropsy findings in the meningitic form in pigs include turbidity of the cerebrospinal fluid, congestion of meningeal vessels and the accumulation of white, purulent material in the subarachnoid space. Occasionally this exudate blocks the flow of cerebrospinal fluid in the ventricular system, causing internal hydrocephalus. Histologically there is infiltration of the affected tissue by large numbers of neutrophils, usually accompanied by fibrin deposition.

**Samples for confirmation of diagnosis**

- Bacteriology – culture swabs from joints, meninges, suppurative foci,
tissue pieces of valvular lesions, lung, spleen, synovial membrane (CULT).
- Histology – formalin-fixed samples of a variety of organs, including brain, lung, spleen, liver (L.M).

**DIFFERENTIAL DIAGNOSIS**

Omphalophlebitis and supplicative arthritis in foals may be due to infection with *Escherichia coli*, *Actinobacillus equuli* or *Salmonella abortoqueina*, but these infections tend to take the form of a fatal septicemia within a few days of birth whereas streptococcal infections are delayed in their onset and usually produce a polyarthritis. In pigs there may be sporadic cases of arthritis due to *Staphylococcus* but the streptococcal infection is the common one. Arthritis due to *Mycoplasma hyorhinis* is less supplicative but may require cultural differentiation. Glasser’s disease occurs usually in older pigs and is accompanied by pleurisy, pericarditis, and peritonitis. Erysipelas in very young pigs is usually manifested by septicaemia. Nervous disease of piglets may resemble arthritis on cursory examination but there is an absence of joint enlargement and lameness. However, the meningitic form of the streptococcal infection can easily be confused with viral encephalitides. Meningitis in young calves may also be associated with *Pasteurella multocida*. Polyarthritis in calves, lambs, and piglets may also be associated with *Arcanobacterium pyogenes* and *Fusobacterium necrophorum*. *S. suis* type 2 can also be the cause of meningitis in older pigs at 10–14 weeks of age. The response of streptococcal infections to treatment with penicillin is of value in the differentiation of the arthritides, and the microscopic and histological findings at necropsy enable exact differentiation to be made. In lambs, supplicative arthritis occurs soon after birth and after docking. The other common arthritides in the newborn lamb is that associated with *Erysipelothrix rhusiophora* but this usually occurs later and is manifested by lameness without pronounced joint enlargement. Calves may also develop erysipelas arthritides.

**TREATMENT**

Penicillin is successful as treatment in all forms of the disease provided irreparable structural damage has not occurred. In newborn animals the dosage rate should be high (20 000 IU/kg body weight (BW)) and should be repeated at least once daily for 3 days. If suppuration is already present, a longer course of antibiotics will be necessary, preferably for 7–10 days. Piglets treated early in the course of the disease will survive but may run. Because of the common litter incidence in piglets and the occurrence of subclinical bacteremia it is wise to also treat all littermates of affected piglets. Benzathine or benzathene penicillins can be used in conjunction with shorter-acting penicillins. General aspects of treatment of the newborn are dealt with in Chapter 3.

**CONTROL**

The principles of control of infectious diseases of the newborn are described in Chapter 3. Because the most frequent source of infection in foals is the genital tract of the dam, some attempt should be made to treat the mare and limit the contamination of the environment. Mixed bacteria have been widely used to establish immunity in mares and foals against this infection but no proof has been presented that they are effective. On heavily infected premises the administration of long-acting penicillin at birth may be advisable. A major factor in the control of navel- and joint-ill in lambs is the use of clean fields or pens for lambing. In pigs, lambs, and piglets may also develop erysipelatous arthritis. 

**REFERENCES**

**STREPTOCOCCUS SUI INFECTION OF YOUNG PIGS**

**ETOLOGY**

There are three organisms that infect the neonatal pig quite commonly – *Haemophilus parasuis*, *S. suis*, and *Actinobacillus suis*, which have been dubbed the ‘suis-cides’. *S. suis* is therefore one of the early colonizers of the pig and by the end of the nursery period most pigs are infected. These authors suggested that virulence may be an attribute of strains that colonize the young pig poorly but infect older animals more easily in the absence of maternal antibody. *S. suis* type 1 and *S. suis* type 2 were the original capsular types of the organism, which appeared to account for most epidemics of the disease. *S. suis* types are subgroups of Lancefield’s group D. There are now at least 34 known *S. suis* capsular types. Even now, new species of streptococcus, such as *S. ferus*, are being isolated from pigs.

**EPIDEMIOLOGY**

The epidemiology of *S. suis* is very complex; there is a great genetic heterogeneity of *S. suis*. The isolation of different strains within the same herd and the predominance of particular strains within some herds are evidence that infection by *S. suis* is a dynamic process and reinforces the idea that the epidemiology is complex.

**Occurrence**

Diseases associated with *S. suis* occur worldwide, affecting pigs less than 2 weeks of age and up to 22 weeks of age. Most cases occur within a few weeks after weaning which is associated with stresors such as moving, mixing, overcrowding, and inadequate ventilation. *S. suis* type 2 causes outbreaks of meningitis in young pigs 10–14 days after weaning. The disease occurs most commonly in recently weaned piglets.
in other countries, causing septicemia, arthritis, and meningitis. In Finland, the most common types isolated from dead pigs were 7, 3, and 2 respectively, and they were most frequently isolated from cases of pneumonia. In the Netherlands, type 2 was most frequently isolated from pigs with meningitis. S. suis type 9 and S. suis type 2 have been isolated as the cause of septicaemia and meningitis in weaned pigs in Australia. The organism has been isolated from a wild sow affected with pneumonia and from a young wild boar.

### Morbidity and case fatality

The incidence of clinical disease ranges from 0–15%. In a 3-year survey of a breeding herd, the combined morbidity and mortality rates due to meningitis from S. suis type 2 were 3%, 8%, and 9.1%, respectively, in each of the 3 years.

### Methods of transmission

The organism is carried in the tonsils and occasionally in the nose of healthy pigs, and transmission to uninfected pigs can occur within 5 days of mixing. The introduction of breeding gilts from infected herds results in disease appearing subsequently in weanlings and growing pigs in the recipient herds. The detectable carrier rates in different groups of pigs can vary from 0–80% and are highest in weaned pigs aged 4–10 weeks. Over 80% of the sows in an individual herd may be subclinical carriers. They do not normally carry the organism in the nasal cavity but in the vagina. Based on the results of sampling of sows and piglets at parturition, and being able to culture multiple serotypes of the organism from the sow’s vaginal secretions and oopharyngeal samples of piglets, it is highly probable that the newborn piglet is infected during birth by the organism, which is transferred from the sow’s vagina to the oral cavity of the piglet. However, even though most pigs are colonized by weaning age, colonization by the virulent strains of S. suis type 2 takes longer and usually does not occur before 15 days of age. This could constitute a risk factor for developing disease later when maternal immunity has waned.

Weaned carrier pigs transmit the infection to previously uninfected pigs after mixing following weaning. The organism can persist in the tonsils of carrier pigs for more than 1 year, and in the presence of circulating opsonic and binding antibodies, and in pigs receiving penicillin-mediated feed. Thus the organism can be endemic in some herds without causing recognizable clinical disease. House flies can carry the organism for at least 5 days and can contaminate feed for at least 4 days.

The carrier rate in some surveys of slaughtered pigs ranges from 32–50% of pigs 4–6 months of age, which may be associated with the high incidence of S. suis type 2 meningitis in humans in the Netherlands. The organism is a potential hazard for abattoir workers, particularly éviscerators who remove the larynx and lungs from carcasses, who have a significantly higher risk of exposure to S. suis than other workers.

S. suis type 2 has also been isolated from pigs affected with bronchopneumonia, usually secondary to enzootic pneumonia, from cases of pleuropneumonia, arthritis, vaginitis and aborted fetuses, and in neonatal piglets 1–2 days of age affected with fatal septicemia. It appears that the organism is found in the lungs of pigs affected with pneumonia more frequently in North America than in other countries. Although airborne infection of type 2 has been described it is said that indirect transmission is a much better way to infect piglets.

The organism is easily transmitted via fomites. It can survive in feces for 104 days at 0°C and for 10 days at 9°C, and in dust for 54 days at 0°C and 25 days at 9°C. Experimentally, pure cultures of the organism placed on rubber and plastic surfaces, especially when protected by swine manure, are viable at up to 55°C and can survive if kept frozen for up to 10 days. The organism is readily destroyed by disinfectants. It can be spread by contaminated pig nose sponges and needles used for blood sampling.

### Risk factors

#### Animal risk factors

The host factors that render pigs susceptible to human disease are uncertain. Over 30 different Gram-positive bacterial organisms may occur in the nasal cavities and tonsils of unweaned pigs of between 2 weeks and 6 weeks of age.

It is suggested that strains of S. suis type 2 vary in pathogenicity, and that the occurrence of disease is dependent on both exposure to a pathogenic strain and undefined secondary factors. The peak incidence of the disease from 5–10 weeks of age suggests that the stressors of weaning may render pigs susceptible to clinical disease. The presence of other infectious diseases such as porcine reproductive and respiratory syndrome (PRRS) and Actinobacillus pleuropneumoniae may be associated with a higher than average prevalence of infection with S. suis. PRRS certainly increases susceptibility to S. suis infection experimentally. In utero infection with PRRS makes pigs more susceptible to subsequent neonatal S. suis infections. Infection of specific-pathogen-free pigs with PRRS virus may be a risk factor for infection and disease associated with S. suis. Similarly, the pseudorabies virus may
Environmental and management factors The incidence of clinical disease appears to depend on environmental factors such as inadequate ventilation, high population density, and other stressors. Several environmental and managemental risk factors have been associated with a high prevalence of pigs harboring *S. suis* in swine herds. Excessive environmental temperatures have been noted in the nursery pig facilities as the most common factor. Nursery pig environmental temperatures should not fluctuate more than 1.1–1.7°C over a 24-hour period to prevent chilling of pigs. Fluctuations in temperature are caused by drafts, inadequate heaters, or poorly insulated buildings. Excessive relative humidity was also a factor, the recommended range for nursery pigs is 35–70%. The third and fourth most common factors were age spread of more than 2 weeks for pigs in the same room, and crowding. The fifth most common factor was the use of continuous flow facilities, which allows for build-up of dust and manure and increased infection pressure. An unusual case where *S. suis* was isolated from the lumen of the small intestine occurred when a feed was formulated with no salt and 58.5 kg instead of 3.5 kg of vitamin premix. Once the ration was corrected the problem disappeared.

Pathogen risk factors There are now at least 34 serotypes of *S. suis*. The organism is divided into serotypes by the antigenic specificity of its capsular polysaccharide. The capsule, certainly for *S. suis* type 2, plays an important role in pathogenesis. As described under Methods of transmission, colonization of piglets occurs very early in life, most pigs being colonized by weaning age; virulent strains of *S. suis* type 2 may not colonize until later. Early colonization reduces the subsequent clinical signs. Despite the association of bacteria with disease, they may also be recovered from the nasal cavities and tonsils of healthy pigs. High numbers of organisms were isolated from the cerebrospinal fluid of clinically normal pigs. A study also showed that a persistent epidemic strain of *S. suis* was consistently isolated from the brains of pigs over a 2-year period, all with a similar genetic pattern.

There are differences in pathogenicity between serotypes and between strains of the same serotype. In the UK there are differences in pathogenicity between types 1 and 2, type 1 causing less severe disease in piglets while type 2 causes a more severe and acute disease in older and growing pigs. Highly virulent and completely avirulent type 2 strains exist. Different strains of *S. suis* type 2 vary in their ability to cause meningitis. Streptococci require manganese but not iron as a growth factor, which affects the activity of superoxide dismutase in cell cultures.

The virulence markers of the organism include the structural proteins muramidase-released protein (MIP) and extracellular protein (EF). It has also been said that they are not essential for virulence. *S. suis* produces four proteases. Fibrinogen-binding protein played a role in the colonization of specific organisms involved in a *S. suis* infection. A secreted nuclease has also been described. An IgG binding protein in the 60 kDa range has been shown to bind IgG in a nonimmune way. Recently, 36 environmentally regulated genes have been identified. There are virulence differences between strains of the same serotype based on the presence or absence of muramidase-released proteins. *S. suis* type 2 from Europe are genotypically different from those of North America. Most Canadian field isolates of *S. suis* type 2 do not produce these virulence-related proteins. An extracellular protein with hemolytic properties, called suilysin, has been described. Most type 2 field strains from four different European countries produce this hemolysin. Between 58 and 90% of strains from the Netherlands, Denmark, France, England, and Italy produce the suilysin but only 1% of Canadian strains do. A total of 164 field isolates from diseased pigs in four countries were serotyped and tested for suilysin. *S. suis* type 2 was the most prevalent type isolated from all four countries. After type 2, type 9 was most prevalent in the Netherlands and France and type 7 in Denmark. All the English isolates were type 2. No nonvirulent suilysin-producing *S. suis* type 2 strains have been reported.

The hemolysin gene was found in over 80% of the strains that were associated with meningitis, septicaemia, and arthritis but with only 44% of pneumonia isolates. The organism bears fimbriae and the capsular materials from different serotypes have distinct morphologies. Certain strains possess hemagglutinating properties. The type 2 isolates possess a factor that allows them to adhere to porcine lung. Restriction endonuclease techniques are being used to examine the genomic structure of the organism, which could be useful for epidemiological monitoring of outbreaks of the disease. A 44 kDa protein has been isolated as a virulence marker of *S. suis* type 2, and the presence of antibodies against this protein appears to be necessary to obtain complete protection against the disease.

Australian isolates of *S. suis* are genetically very diverse, which suggests that serotyping is not a reliable technique for identifying specific strains and not a good predictor of the genetic background of a given isolate. Some isolates of *S. suis* have developed resistance to penicillin and tetracycline, which may reflect the usage of these antimicrobials in treatment and control programs.

*S. suis* type 2 can survive in feces for 104 days at 0°C (32°F), up to 10 days at 9°C (48°F) and up to 8 days at 22–25°C (71–77°F). It can survive in dust for up to 25 days at 9°C (48°F) but could not be isolated from dust stored at room temperature for 24 hours. The organism is rapidly inactivated by disinfectants commonly used on farms. Liquid soap inactivates *S. suis* type 2 in less than 1 minute at a dilution in water of 1 in 500. The organism can survive in pig carcasses at 40°C (104°F) for 6 weeks, which may be an important source of the organisms for infection in humans.

Zoonotic implications Splenectomized humans are particularly at risk from certain infections, including streptococci. Infections with *S. suis* type 2 are the most common infections in humans and occur most commonly in people having contact with pigs or raw pork. It is possible that many human cases are misdiagnosed, such as were described in south-east Asia, where five of eight cases of *S. suis* were described as *S. viridans*. A truck driver has recently been described with septic shock. In the UK the highest incidence of meningitis due to *S. suis* type 2 is in butchers and abattoir workers; transmission is thought to be mainly via minor skin abrasions. The clinical manifestations include meningoitis and septicaemia, which may be accompanied by arthritis, endocarditis, and disseminated intravascular coagulation. Endocarditis and acute gastroenteritis have also been reported. In a series of 35 human cases of *S. suis* type 2 meningitis in the UK from 1975–1990, deafness occurred in 50% of patients, vertigo and ataxia in 30% and arthritis in 53%. There was a case fatality rate of 13%. The organism invades the cerebrospinal fluid within monocytes, an example of the 'Trojan horse' mechanism of entry. Deafness may follow in 50–60% of cases and is due to cochlear sepsis following invasion of the organism from the subarachnoid space into the perilymph of the inner ear. Subclinical infection in pigs sent to slaughter represents a potential source of infection for abattoir workers, eviscerators who remove the larynx and lungs have a significantly higher risk of exposure to the organism than other abattoir workers. Within infected herds in New Zealand, up
to 100% of pigs are carriers and S. suis type 2 infection may be one of the most infectious potentially zoonotic pathogens present in New Zealand, although very rarely resulting in clinical disease.70 The annual incidence of subclinical infection and seroconversion in pig farmers in New Zealand is close to 28%.

PATHOGENESIS

Streptococci exist in extremely different phenotypes with regard to adhesion, invasion and cytotoxicity. These features depend on the state of encapsulation and environmental growth conditions.71

The tonsils are a site of persistence, multiplication and portal of entry of a variety of pathogens including S. suis.72

The organism resides in the crypts of the palatine tonsils. Invasive disease occurs in a minority of infected pigs, following entry of organisms into the systemic circulation as a bacteremia and then septiciemia, leading to a meningitis.73 Most bacteria remain extracellular, with fewer than 2% of monocytes containing bacteria. There is a high level of adhesion of bacteria to phagocytic cells. S. suis adheres to brain microvascular endothelial cells and suilysin can damage these.74 It has been shown that S. suis capsular strains stimulate tumor necrosis factor alpha (TNF-α) and interleukin (IL)-6 but that the suilysin and the extracellular protein do not do so on their own.75 A terminal acute fatal septicemia is the common outcome in young animals, but in older animals localization can occur in synovial cavities, endocardium, eyes, and meninges. A persistent bacteremia is an important phase in the pathogenesis of S. suis type 2 meningitis. Virulent isolates of S. suis type 2 possess capsules and are relatively resistant to phagocytosis.76 Isogenic mutants defective in capsule production were not virulent.77 S. suis is able to adhere to but not to invade epithelial cells and the adhesins are partially blocked by the capsule and are part of the cell wall.78 The highly virulent isolates possessed the suilysin, muramidase releasing protein and extracellular protein factor phenotype.79 S. suis are able to survive and replicate within macrophages, and the bacteria enter the cerebrospinal fluid space in association with migrating monocytes, which move through choroid plexuses.80 They therefore enter the cerebrospinal fluid by a 'Trojan horse' mechanism similar to that used by some viral pathogens of the central nervous system.81 The predominant lesions are supplicative or fibrinopurulent inflammation in brain, heart, lungs, and serosa.82 S. suis type 9 may produce a different distribution of lesions compared to type 2.83

The disease has been reproduced experimentally in pigs and laboratory animals by intravenous, intranasal, and subarachnoid routes.84 Certain strains of S. suis can cause vascular lesions, with the development of fibrinohemorrhagic pneumonia and septal necrosis.85 Of importance in the pathogenesis of S. suis infections is the predisposing role of PRRS. This effect of PRRS has only been experimentally demonstrated with S. suis.86

CLINICAL FINDINGS

Multiple Streptococcus spp. are implicated in lameness and central nervous system signs in piglets and sows.86 There is significant variation of carrier states and clinical signs with the individual serotypes.87

Arthritis and meningitis may occur alone or together and are most common in the 2-6-week age group. More commonly several piglets within a litter are affected. Meningitis is associated with serotypes 1, 2, 1/2, 3, 4, 8, 9, 14, and 16; septiciemia with 2; arthritis with 7 and 14; abscesses with 2; bronchopneumonia with 2, 3, 7, 10, 15, and 27; reproductive damage with 2, 13, and 22; and 14 can be associated with any clinical condition.88

The arthritis is characterized by enlarged and distended joint capsules, lameness and pain on palpation of the affected joints. Fever, depression, reluctance to move, and inactivity are common.

Meningitis is characterized by a fever, anorexia, and depression. The gait is stiff, the piglets standing on their toes, and there is swaying of the hindquarters. The ears are often retracted against the head. Blindness and gross muscular tremor develop followed by inability to maintain balance, lateral recumbency, violent paddling, and death. In many cases there is little clinical evidence of omphalophlebitis.

In epidemics of meningitis due to S. suis type 2, sudden death in one or more pigs may be the first sign. Affected pigs found alive are incoordinated and rapidly become recumbent. There is opisthotonos, paddling and convulsions and death in less than 4 hours. A fever of up to 41°C (105°F) is common. In the UK, meningitis of recently weaned pigs is the most striking feature of S. suis type 2 infection.

Otitis interna is a common sequela to many cases of S. suis meningitis.89

Arthritis is common in younger pigs.

In endocarditis and septiciemia the piglets are usually found comatose or dead without premonitory signs having been observed.

Valvular endocarditis due to S. suis type 2 has also been reported in a 13-week-old fatten pig in a breeding herd that had a long history of streptococcal meningitis.90

CLINICAL PATHOLOGY

Culture or detection of organism

The organism can be cultured from joint fluid, cerebrospinal fluid, blood, brain, and lungs of pigs at necropsy. The tonsils of live pigs may be swabbed and cultured for the organism. Improved and selective media are available for the isolation and serotyping of the organism.91 An indirect fluorescent antibody test can be used to identify the organism on tonsillar swabs of live pigs. Because of multiple antimicrobial resistance among strains of the organism, drug sensitivity testing on a routine basis is recommended.92 Highly virulent strains of S. suis types 2 and 1 were detected in tonsillar specimens using PCR.92 Rapid serotype-specific PCR assays have been developed.93

Serology

The specific serotype of S. suis should be determined. A simplified laboratory method is available for the identification of S. suis strains associated with different animal hosts or located in different body regions.94 An enzyme-linked immunosorbent assay (ELISA) using monoclonal antibodies directed against virulence markers of S. suis can distinguish between virulent and avirulent strains of the organism.95 A rapid and specific double-sandwich ELISA is available for the detection and capsular typing of the organism with a specificity of 97.6% and sensitivity of 62.5%.96 However, many laboratories are not readily equipped to identify the numerous serotypes of the organism. The biochemical characteristics and serotyping techniques have been described.97

NECROPSY FINDINGS

In pigs dying from S. suis type 2 infection, the gross and microscopic findings include one or more of fibrinopurulent polyserositis, fibrinous polyarthritis, fibrinous or hemorrhagic bronchopneumonia, suppurative meningitis, hemorrhagic necrotizing myocarditis, and vegetative valvular endocarditis.98 Gross myocardial lesions cannot be distinguished from those of mulberry heart disease. In cases with meningitis, there is turbidity of the cerebrospinal fluid, congestion of meningeal vessels, and variable amounts of white exudate in the subarachnoid space. This suppuration is usually most evident along the ventral aspect of the brain. The typical histological picture is one of acute inflammation – neutrophils and fibrin dominate the response. Other changes that may be observed in S. suis infections of the central nervous system include internal hydrocephalus, foci of liquefactive necrosis, subacuete (mononuclear cell-rich) meningencephalitis or meningencephalomyelitis with bilateral subacute optic neuritis and Gasserian ganglion neuritis.99 In the tonsils, S. suis organisms can be seen in the subepithelial lymphoid tissue and in the crypt lumen and crypt epithelium.100 S. suis type 9 is more prone to cause
bronchopneumonia than the spectrum of lesions typical of type 2.82

Samples for confirmation of diagnosis
- Bacteriology – lung, spleen, culture swabs from serosal surfaces, joints, meninges. Cerebrospinal fluid is the material for the best diagnosis (CULT). Bacterial culture is difficult if the animals have been treated and this is so even when they receive growth-promoting antibiotics.97
- Histology – formalin-fixed samples of a variety of organs, including lung, brain, heart, liver (LM). Immunohistochemistry and in situ hybridization have been described for use on formalin-fixed tissue and are able to detect single cells.99

(Note the zoonotic potential of this organism when handling carcass and submitting specimens.)

Differential Diagnosis

In pigs there may be sporadic cases of arthritis due to staphylococci but the streptococcal infection is the common one. Arthritis due to M. haemolytica is less suppurative but may require cultural differentiation. Glasser's disease occurs usually in older pigs and is accompanied by pleurisy, periartitis, and peritonitis.

Erysipelas in very young pigs is usually manifested by septicemia. Nervous disease occurs in pigs older than 12 weeks of age and is accompanied by pleurisy, periartitis, and peritonitis.

Penicillin has been the treatment of choice but penicillin-resistant isolates have emerged. Penicillin sensitivity can no longer be assumed for all strains of S. suis and the routine use of penicillin must be re-evaluated.103 In one study, more than 50% of isolates of S. suis were not susceptible to penicillin.91 Penicillin did not eliminate the organism from the tonsils of carrier pigs treated daily for several days.104 In some surveys, the antimicrobial sensitivity of S. suis indicates a high degree of sensitivity to ampicillin, cephalothin, and trimethoprim–sulfamethoxazole, and resistance to the aminoglycosides gentamicin and streptomycin.91 It is recommended that trimethoprim–sulfamethoxazole be used for the treatment of affected pigs and be given daily for 3 days. An occasional strain may be resistant to trimethoprim–sulfamethoxazole.

None of the resistant strains produced beta-lactamase. Conjugation of antibiotic resistance in S. suis has been reported, which may explain the multiple antimicrobial resistance.105 The genes responsible for resistance appear to be homologous to genes found in many other species of bacteria.106 Treatment of pigs affected with meningitis due to S. suis type 2 with either trimethoprim–sulfadiazine or penicillin reduced the case fatality rate from 55% to 21%. Ceftiofur has been shown to improve cure rates (67%) compared to ampicillin (55%) and to reduce mortality from 35% with ampicillin to 24% with ceftiofur.107

Passive immunization against S. suis type 2 has been described.108

CONTROL

At the present time there are no known specific methods for the prevention of the disease complex associated with S. suis type 2. The recommendations are based on empirical field observations.

It has been suggested that ceftriaxone administered by injection for three consecutive days following S. suis challenge was the most effective regimen for minimizing disease associated with PRRS virus and S. suis infection.109

Environment and management

Good management and hygiene techniques should be emphasized. Based on observations of the effects of management practices on S. suis carrier rate in nursery pigs, excessive temperature fluctuations, high relative humidity, crowding, and an age spread exceeding 2 weeks of pigs in the same room were associated with a higher-than-average percentage of carrier pigs.

Nursery pig environmental temperature should not fluctuate more than 1.1–1.7°C over a 24-hour period.34 Excessive relative humidity must be avoided; the recommended range of relative humidity for nursery pigs is 55–70%.

The age spread between pigs in the same room should not exceed 2 weeks. Young, potentially naive piglets raised in the same air space as older animals may be exposed to high concentrations of the organism.

Adequate space to avoid crowding is also necessary. Crowding occurs when less than 0.18 m² is provided for each 22.7 kg of pig.34 The use of an all-in, all-out production system is recommended, compared to a continuous flow system, which allows for a buildup of pathogens. The control of the most commonly encountered infectious diseases is also important. A well-fortified nutritional program may also aid in the control of S. suis infection and the carrier state in a swine herd.

Segregated early weaning programs have been used in an attempt to control the disease but appear to be unsuccessful in reducing the carrier state.110 Pigs are weaned at an early age and moved to a separate site in an effort to separate the piglets from the sows, which are the primary source of the organism. Carrier pigs readily transmit the infection to uninfected pigs and the main method of spread between herds is the movement of infected breeding stock or weaner pigs. In herds that are free of the infection, it is necessary to avoid the importation of infected pigs. Eradication of S. suis type 2 infection can be attempted by depopulation of suspect carrier sows and replacement with noninfected breeding stock.

Mass medication of feed

Mass medication of individual pigs or medication of the feed during periods of high risk may control the incidence of clinical disease. Outbreaks in sucking piglets have been controlled by a single injection of penicillin on the day of birth. This treatment is not recommended for young pigs, as the high mortality rate may be due to a central nervous system infection, hydrocephalus, or meningoencephalitis.111

In the first days after weaning, subclinical meningitis has been seen in nursery pigs,112 and in pigs with granulomaly.69

importance because of the losses due to rejection of infected carcasses at meat inspection.

The condemnation rate of pig heads at slaughter may be as high as 78–94% in some herds. However, based on annual reports from the Federal Meat and Poultry Inspection Service in the USA, the incidence of jaw abscesses in pigs declined steadily to a level in 1981 less than one-third of the peak incidence 20 years earlier.1 This may be due to changes in management of pig herds and the use of antibiotic feeding.

Most jaw abscesses in swine are associated with beta-haemolytic streptococci of Lancefield’s group E type IV,12 although P. multocida, E. coli, and A. pyogenes may also be present. Some additional serotypes have been isolated.1 This disease occurs primarily in postweaning and fattening swine. Piglets under 28 days of age are relatively resistant and even colostrum-deprived piglets are resistant to clinical disease following experimental infection.4

The disease has been produced by feeding or the intranasal or intrapharyngeal instillation of streptococci5 and they are thought to be the cause, infection occurring through the pharyngeal mucosa from contaminated food and water.6 In herds where cervical abscess is a problem, streptococci can commonly be isolated from the vaginas of pregnant sows and the pharynges of normal young pigs.7 The persistence of the infection in herds is thought to depend on the presence of carrier animals.8 Transmission occurs via feed and drinking water. After infection has occurred a bacteremia develops and abscesses are initiated in the cervical lymph nodes in a high proportion of pigs.9 Infrequently, abscesses occur in atypical sites other than the head and neck. Pigs that have recovered from the natural disease are immune to experimental challenge.10 A microtiter agglutination test is available to detect infections associated with type IV streptococci.11

Vaccination of pregnant sows with an autogenous or commercial bacterin containing streptococci and staphylococci is thought to be of value in protecting the litters of the vaccinated sows.12 Vaccination of young pigs with a whole-culture bacterin has provided some protection, but the use of an oral vaccine prepared from an avirulent strain of group E streptococci and sprayed into the oropharynx is highly effective as a preventive measure.13 A number of prophylactic regimens based on the feeding of antibiotics have been proposed and generally give good results. Chlorotetracycline fed to young pigs at the rate of 220 g/tonne for 1 month is an example.14 Treatment of breeding pigs at the rate of 10 g/kg body weight is also effective in reducing the severity of exposure to the young pigs to infection. A similar advantage can be gained by keeping the treated groups isolated from untreated groups of older pigs. Because piglets under 28 days of age are relatively resistant to clinical disease, the weaning and isolation from older pigs is a successful control program.

REFERENCES

Diseases associated with Staphylococcus species

Masitis associated with Staphylococcus aureus is dealt with in Chapter 15, udder impetigo of cattle in the section on miscellaneous abnormalities of the udder, and staphylococcal pyoderma of horses under the heading of dermatitis. Other miscellaneous infections include:

- Tick pyemia of lambs (see below)
- Exudative epidermitis of pigs (see below)
- Staphylococcal septicaemia of the newborn, especially lambs. This is a relatively common disease and may have a significant mortality rate, partly due to a high incidence of myocardial lesions. In most cases the navel appears to be the portal of infection but infection may also occur through marking wounds
- Periorbital eczema. A severe supplicative ulceration of the skin around the eyes, ears, nasal and maxillary area and the base of the horns occurs in adult sheep.13 Lesions may be unilateral or bilateral and manifest with hair loss and erythematous swelling, initially covered by a serosanguinous exudate and eventually by a red-brown scab. The disease is associated with S. aureus and may be predisposed by trauma from aggression where there is inadequate trough feeding space, or by grazing over corn stalks or other abrasive pastures. Lesions persist for 4–5 weeks but a shorter course is seen with local and parenteral antibiotic therapy.
- A benign folliculitis of the face of sucking lambs.14 A more severe facial dermatitis is reported in 6-month-old lambs associated with a combined infection with S. aureus and contagious pustular dermatitis,5 which responded well to treatment with procaine penicillin.
- Dermatitis of the legs of sheep with most lesions close to the coronet6
- An outbreak of skin abrasion associated with S. aureus infection following shearing7
- Staphylococcus hyicus, the causative organism of exudative epidermitis of pigs, is also an occasional cause of a scabby dermatitis, accompanied by itching and alopecia, on the skin of the neck and back of donkeys and horses8
- Impetigo with a superficial pustular dermatitis at the base of the teats, on the udder, in the intramammary sulcus and in the perineal area occurs in goats associated with either Staphylococcus intermedius, S. aureus, or Staphylococcus chromogenes.9 Good response to a single dose of tilimicosin (10 mg/kg BW administered subcutaneously) is reported10
- A generalized dermatitis in young lambs with clinical similarities to exudative epidermitis in pigs but associated with Staphylococcus xylosus.11

TICK PYEMIA OF LAMBS (ENZOOTIC STAPHYLOCOCCOSIS OF LAMBS)

Synopsis

Etiology Infection with Staphylococcus aureus predisposed by infection with Anaplasma (formerly Ehrlichia) phagocytophila

Epidemiology Disease of young lambs that occurs in areas that are habitats for Ixodes ricinus

Clinical and necropsy findings Septicaemia and subsequent abscession in internal organs

Diagnostic confirmation Isolation of organism

Treatment Long-acting antimicrobials

Control Tick control
ETIOLOGY
The disease has a complex causality and results from a septicaemia produced by *S. aureus* predisposed by infection with *Ehrlichia* (Cytopreotes) *phagocytophila*, which is transmitted by *Ixodes ricinus*.1

EPIDEMIOLOGY
Enzootic disease has been recorded only in the UK and occurs only in the hill areas that are habitats for the tick *I. ricinus*. The disease occurs in the spring and early summer. The annual incidence varies with the year and between farms. On average, 5% of lambs at risk are affected but on some farms the incidence may be as high as 29% in certain years.2

In enzootic areas the disease has considerable economic importance and has been stated to affect as many as 300,000 lambs every year, the majority of which die or fail to be profitable.3

PATHOGENESIS
Experimental and epidemiological studies have established a clear relationship between infection with *E. phagocytophila*, the agent of tick-borne fever, and susceptibility to infection with *S. aureus*.1 The role of the tick is in the transmission of *E. phagocytophila*.1

Infection with *E. phagocytophila* produces a significant lymphocytopenia that develops 6 days after infection and affects all subsets of T and B lymphocytes, and also a prolonged neutropenia lasting for 2-3 weeks combined with a thrombocytopenia. Up to 70% of the neutrophils are parasitized from the onset of the parasitemia and have impaired function, and lambs with tick-borne fever have a much higher susceptibility to experimental infection with *S. aureus* than do non-infected lambs.3 The ticks are not thought to necessarily provide portals of entry for, nor to be the primary carriers of, the infection with *S. aureus*, although they are important in this respect.3 *S. aureus* can gain entry through a variety of sources and in affected flocks there is a high incidence of lambs carrying the same infection on their nasal mucosa.4

CLINICAL AND NECROPSY FINDINGS
Lambs aged 2-10 weeks are affected. They may die quickly of septicemia or show signs of localization of infection. Clinically this is most evident by infections that localize in joints or the meninges to manifest as arthritis or meningitis but on postmortem examination abscesses can be found in any organ, including the skin, muscles, tendon sheaths, joints, visera, and brain.

TREATMENT AND CONTROL
Treatment of the established disease has limited value and efforts should be directed at prevention or mitigation of early infection during the bacteremic phase.

The strategic use of long-acting antibiotics has shown success in this respect. On farms with enzootic disease, benzathine penicillin administered at 3 weeks of life has been shown to result in a marked decrease in the incidence of subsequent clinical disease.5 The use of long-acting tetracyclines has the additional advantage of protecting against infection with the agent of tick-borne fever as well as *S. aureus* infection; two treatments of lambs, the first between 1 and 3 weeks of age and the second between 5 and 7 weeks, has been shown to result in a significant reduction in morbidity and mortality.6 In addition, the treatment has been accompanied by increased weight gain.

**Tick control** by dipping lambs in an organophosphatidic insecticide every 3 weeks significantly reduces the incidence of clinical disease and increases weight gain of clinically normal lambs. Separation of the lambs for dipping has not been associated with problems of mis-mothering.1

Pour-on preparations on the lambs are also successful.2 A combination of antibiotic and acaricide treatment may be the most effective and in one trial reduced losses from 10.3% to 0.6%.2 Dipping the whole flock in an acaricide in spring, whereas it will not completely eradicate tick infestation, will reduce the incidence of tick pyemia.

Pyemic infection with *S. aureus* is also recorded in association with tick infestation in camels in Saudi Arabia.6

EXUDATIVE EPIDERMISIS
(GREASY PIG DISEASE)

ETIOLOGY
The condition of exudative dermatitis is similar to staphylococcal scalded skin syndrome in humans associated with *S. aureus.*

**Staphylococcus hyicus** is the cause of exudative epidermitis in suckling and weaned piglets.2 It also causes several other diseases sporadically in different animal species; bacteruria in pigs, polyarthritis in pigs,3 abortion in pigs, flank biting and necrotic ear lesions,4 and pneumonia.3

In other species it has been associated with skin infections in horses, donkeys, and cattle, subclinical mastitis in cows and osteomyelitis in heifers.2

A second species, *Staphylococcus chromogenes*, is part of the normal skin flora of pigs,6 cattle, and poultry. It had been considered nonpathogenic until exudative epidermitis was associated with it in 2005.5 These strains also produced exfoliative toxin type B (ExLB), which was identified by PCR.

**ETIOLOGY**

**Staphylococcus hyicus**

**Epidemiology** Affects suckling and weaned piglets under 6 weeks of age; peak incidence under 1 week of age. Morbidity 20-100%; case fatality 50-75%. Organism carried by sow

**Signs** Marked cutaneous erythema and pain, dehydration, extensive greasy exudate; peracute cases die; less severe cases may survive

**Clinical pathology** Bacterial culture of skin

**Necropsy findings** Exudative epidermitis, degenerative changes in kidney

**Diagnostic confirmation** Culture of organism

**Differential diagnosis** See Table 16.3

**Treatment** Penicillin parenterally

**Control** Sanitation and hygiene of pens. In outbreaks, isolate affected piglets and sows
Diseases associated with *Staphylococcus* species

<th>Disease</th>
<th>Epidemiology</th>
<th>Clinical and laboratory findings</th>
<th>Response to treatment</th>
</tr>
</thead>
<tbody>
<tr>
<td>Swine pox</td>
<td>Mainly sucking piglets. High morbidity but low mortality except in very young piglets. Usually associated with swine house infestation</td>
<td>Papules, vesicles, and circular red-brown scabs on ventral belly wall and over the sides and back. Pox characteristics</td>
<td>None required except for insect and louse control. Spontaneous recovery in 3 weeks</td>
</tr>
<tr>
<td>Skin necrosis</td>
<td>Sucking piglets. High morbidity with abrasive flooring</td>
<td>Abrasion and necrosis starting shortly after birth and reaching maximum severity at about 1 week. Anterior aspect of carpus more common site but also fetlock, hock, elbow, and coronet. Bilateral. Necrosis and erosion of anterior two or three pairs of teats</td>
<td>Usually none required. Recovery 3–5 weeks. Protect area with tape if severe, plus topical antiseptics. Treatment may necrosis will render animal unsuitable for selection and breeding. Correction of flooring</td>
</tr>
<tr>
<td>Exudative epidermitis (greasy pig disease)</td>
<td>Entire litters of sucklings pigs, most severe under 1 week of age, occurs up to 10 weeks, high case fatality in younger pigs</td>
<td>Marked cutaneous erythema with seborrhea, severe dehydration, and death in piglets under 10 days. Older piglets covered with greasy exudate and recover. Staph. hyicus on culture</td>
<td>Piglets under 10 days of age die in spite of therapy. Older pigs may survive with penicillin treatment topicaly and parenterally</td>
</tr>
<tr>
<td>Dermatosis vegetans</td>
<td>Inherited and congenital, high morbidity. High case fatality by 8 weeks</td>
<td>Lesions begin as small red flat plaques which enlarge from 1 to 2 cm diameter with a prominent ring of erythematous skin covered in center by thin, dry, brown, loose scales. Lesions usually coalesce forming a mosaic pattern, especially on belly. Scraping negative. No growth depression</td>
<td>None indicated. Genetic control</td>
</tr>
<tr>
<td>Pyrriasis rosea</td>
<td>One or more piglets in litter after weaning. High morbidity, nil mortality</td>
<td>Erythema and edema of coronets, uneven brite hooves, dry brown crusts on belly wall, giant cell pneumonia. Club foot</td>
<td>None required. Emollient to soothe the lesion. Recovery occurs in 4–8 weeks</td>
</tr>
<tr>
<td>Parakeratosis (zinc deficiency)</td>
<td>Weaners and feeder pigs on diet low in zinc and high in calcium. Herd problem, high morbidity, no mortality</td>
<td>Erythematous areas on ventral abdomen and symmetrically over back and legs develop into thick crusts and fissures. No pruritus. Skin scrapings negative. Growth rate depression</td>
<td>Add zinc to diet 100 ppm. Adjust calcium. Recovery in 2–6 weeks</td>
</tr>
<tr>
<td>Ringworm</td>
<td>Feeder and mature pigs. Usually several pigs within pen or shed. High morbidity with M. nanum in sows</td>
<td>Centrifugally progressing ring of inflammation surrounding an area with scabs, crusts, and brown or black exudate. May reach large size. Bristles usually intact. No pruritus. Positive skin scrapings and hair. No ground depression</td>
<td>Fungicides. In growers spontaneous recovery in 8–10 weeks if well nourished. M. nanum in sows is persistent and responds poorly</td>
</tr>
<tr>
<td>Ulcerative granuloma</td>
<td>Young pigs but all ages. Sporadic infection following abrasion. Poor hygiene</td>
<td>Large swollen tumorous mass with several discharging sinuses. Central slough and ulcer</td>
<td>Fair, depending on site. Surgical removal and/or sulfadimidine and streptomycin</td>
</tr>
<tr>
<td>Sarcoptic mange</td>
<td>All ages of pigs. Herd problem. Reservoir of infection in sows. High morbidity. Nil mortality</td>
<td>Intense pruritus. Mites on scraping. Erythematous spots with scale and minor brown exudation. Especially evident in thin skin areas. Secondary trauma to skin and bristles from rubbing. If severe, intense erythema. Chronic infections, thickening and wrinkling of skin. Depression of weight gain</td>
<td>Good response to vigorous therapy with ascaricides. Treat on herd basis</td>
</tr>
<tr>
<td>Allergic dermatoses to <em>Tyrophagus</em> spp. (harvest mites)</td>
<td>Weaner and feeder pigs few weeks after eating dry ground feed from autonomic feeders</td>
<td>Pinpoint erythematous spots and fragile scales. Intense pruritus. Skin scraping positive for mites</td>
<td>Spontaneous recovery common. Insecticide effective</td>
</tr>
<tr>
<td>Erysipelas</td>
<td>Feeder and adult pigs, occasionally weaners. Variable morbidity. Low mortality if treated early</td>
<td>Small red spots developing to characteristic rhomboidal lesion raised and red in color. Lesions may become jointed and lose their characteristic shape. Progress to necrosis and desquamation. Fever and other signs of septicaemia</td>
<td>Penicillin</td>
</tr>
</tbody>
</table>
typing of *S. hyicus* subsp. *hyicus* isolated from pigs with or without exudative epidermitis revealed two or more phage patterns in the isolates from each pig with the disease and a single-phage pattern in isolates from healthy pigs.\(^\text{13,14}\)

**Risk factors**

Animal risk factors

Field evidence suggests that environmental stress of various kinds, including agalactia in the sow and intercurrent infection, predisposes to the disease. Lesions commonly develop first over the head, apparently in association with bite wounds, which occur when the needle teeth have not been cut or have been cut badly. Other factors include fighting following mixing of litters, excessive humidity over 70%, and following sarcotic mange. The presence of the disease in a swine herd can account for a 35% reduction in the margin of output over feed and veterinary costs over a 2-month period.

Pathogen risk factors

Strains of *S. hyicus* can be divided into virulent and avirulent strains with regard to ability to produce exudative epidermitis in experimental piglets; both types of strain can be isolated simultaneously from diseased piglets.\(^\text{4}\) It has been shown that different types of *S. hyicus* expressing different types of toxin may be present in the same diseased pig.\(^\text{10}\)

*S. hyicus* produces an exfoliative toxin that can be used to reproduce the disease.\(^\text{15,16}\) There are several toxins, including ExLA, ExLB, ExLC, ExLD, SHETa, and SHETb.\(^\text{17}\) The exfoliative toxins from isolates from different countries have recently been described.\(^\text{18}\) Strains of the organism isolated from a large number of Danish pig herds included different electrophoretic motility and plasmomediated antibiotic resistance patterns.\(^\text{19}\)

The antibiotic and plasmid profiles of strains isolated from pig herds may be a reflection of the use of antibiotics in those herds.\(^\text{20}\) Different types of toxin are produced.\(^\text{21-23}\)

Recently the genes encoding for the exfoliative toxins SHETb, ExLA, ExLB, ExLC, and ExLD have been identified\(^\text{24}\) and sequenced.

The condition has been seen more frequently in cases of PRRS and PCV2 infections.\(^\text{25,26}\)

The organism has been found as a frequent inhabitant of the skin of cattle and has been isolated from cattle with skin lesions.\(^\text{27,28}\) Naturally occurring lesions of dermatitis of the lower limbs of horses\(^\text{29}\) and similar lesions over the neck and back of donkeys\(^\text{30}\) have been recorded. Experimentally, the organism can cause lesions in horses similar to those of exudative epidermitis. A concurrent infection with *Dermatophilus congolensis* has also been reported.\(^\text{31}\)

**PATHOGENESIS**

*S. hyicus* has cytotoxic activity for porcine keratinocyte cells in culture, which may indicate one of its virulence factors.\(^\text{32}\)

The exfoliative toxins are actually epidermolsins\(^\text{32}\) that are active against desmoglein-1, which is a desmosomal cadherin-like molecule\(^\text{33}\) involved in cell-to-cell adhesion.\(^\text{34}\) The ExLs can cause blister formation in the porcine skin by digesting porcine desmoglein-1 in a similar way to exfoliative toxins of *S. aureus*.

The earliest lesion is a subcorneal pustular dermatitis involving the interfollicular epidermis. Exfoliation follows with sebaceous exudation and formation of a crust. In the well-developed case there is a thick surface crust composed of orthokeratotic and parakeratotic hyperkeratosis and neutrophilic microabscesses with numerous colonies of Gram-positive cocci.\(^\text{35}\)

Although the principal lesion is an inflammatory-exudative reaction in the corium and upper layers of the epidermis, the disease is probably a systemic rather than a local one. Experimental infection of gnotobiotic pigs leads to dermatitis of the snout and ears, then the medial aspect of the thighs, the abdominal wall and the coronets. The lesions can be produced experimentally by using crude extracellular products and a partially purified exfoliative toxin.\(^\text{36}\)

**CLINICAL FINDINGS**

The morbidity varies from 10–100% and the mortality from 5–90%, with an average of 25%.\(^\text{35}\)

In the pustule form, which occurs most commonly in piglets only a few days of age, there is a sudden onset of marked cutaneous erythema, with severe pain on palpation, evidenced by squealing. Anorexia, severe dehydration, and weakness are present and death occurs in 24–48 hours. The entire skin coat appears wrinkled and reddened and is covered with a greasy, gray-brown exudate that accumulates in thick clumps around the eyes, behind the ears, and over the abdominal wall. In the less acute form, seen in older pigs 3–10 weeks of age, the greasy exudate becomes thickened and brown and peels off in scabs, leaving a deep-pink-colored to normal skin surface. There is no irritation or pruritus. In the subacute form, the exudate dries into brown scales that are most prominent on the face, around the eyes, and behind the ears. In a small percentage of pigs the chronic form occurs and the course is much longer; there is thickening with wrinkling of the skin and thick scabs that crack along flexion lines, forming deep fissures. Most peracute cases die, while piglets with the less severe forms will survive if treated. Some pigs are affected with ulcerative glossitis and stomatitis.

Abortion in a sow has been attributed to the organism.\(^\text{37}\)

**CLINICAL PATHOLOGY**

Bacterial examination of skin swabs may reveal the presence of *S. hyicus*. A phage typing system can be used to determine the presence of virulent strains and to distinguish them from less virulent strains.\(^\text{14}\)

**NECROPSY FINDINGS**

Necropsy of these dehydrated, unthrifty piglets often reveals a white precipitate in the renal papillae and pelvis. Occasionally this cellular debris causes ureteral blockage. Some piglets also have a mild ulcerative glossitis and stomatitis. Microscopically, there is separation of the cells of the epidermis in the upper stratum spinosum, exfoliation of the skin, erythema, and serous exudation. The crusting dermatitis features a superficial folliculitis and a hyperkeratotic perivascular dermatitis with intracorneal pustules and prominent bacterial colonies. Degenerative changes are visible in the renal tubal epithelium.

**Samples for confirmation of diagnosis**

- Bacteriology – samples of acute skin lesions (CULT). The organism forms 3–4 mm white, nonhemolytic colonies on blood agar. It is catalase- and mannitol-negative but hyaluronidase-positive
- Histology – formalin-fixed skin (multiple sites), kidney (LM).

A PCR is available but requires a pure culture and large numbers of organisms to be successful.

**DIFFERENTIAL DIAGNOSIS**

Exudative epidermitis may resemble several skin diseases of pigs of all age groups (Table 16.3). However, in exudative epidermitis there is no pruritus or fever. Careful gross examination of the lesions, particularly their distribution, the state of the hair shaft, the character of the exudate and the presence or absence of pruritus must be considered, along with skin scrapings and biopsies.

**TREATMENT**

Experimentally infected piglets respond favorably to a topical application of cloxacillin 10 000 IU/g of lanolin base and 1% hydrocortisone combined with parenteral cloxacillin. Treatment must be administered as soon as the lesions are visible. Procaine benzylpenicillin at a dose of 20 000 IU/kg BW intramuscularly daily for 3 days is also recommended. The antimicrobial sensi-
activities determined in one field investigation revealed that all isolates were sensitive to novobiocin, neomycin, and cloxacillin. Novobiocin may be the antimicrobial of choice since staphylococci are universally sensitive to this antibiotic. However, there is no available information on the efficacy of antimicrobials for naturally occurring cases of exudative epidermitis. A study has suggested that erythromycin, sulfathiazole, and trimethoprim may be the most useful drugs, whereas penicillin and tetracyclines may not be very useful. Naturally occurring cases in piglets under 10 days of age respond poorly, while older pigs recover with a skin wash using a suitable disinfectant soap. The most successful treatment is antibiotics and skin washing for a period of at least 5–7 days. It is also essential to make sure that there is sufficient dietary provision of zinc, biotin, fat, selenium, and vitamin E in the diet.

CONTROL

The infected accommodation should be cleaned, disinfected and left vacant before another farrowing sow is placed in the pen. Strict isolation of the affected piglets and their dam is necessary to prevent spread throughout the herd. Dead piglets should be removed promptly from the premises and in-contact sows should be washed with a suitable disinfectant soap. Maternal antibodies will protect piglets in the first few weeks of life.

Autogenous vaccines have been used with varying degrees of success. It is important to use a strain that produces the exfoliative toxin, so the recent development of PCRs that identify the genes for toxin development will ensure that the right isolates are used for the autogenous vaccine. It will also facilitate the development of a commercial vaccine.

A novel approach to the control is bacterial interference. Experimentally, the precolonization of the skin of gnotobiotic piglets with an avirulent strain of *S. hyicus* will prevent the experimental reproduction of the disease with the virulent strain of the organism.

REFERENCES

Diseases associated with Corynebacterium, Actinobaculum, and Arcanobacterium species

**Arcanobacterium pyogenes**

*Arcanobacterium* (formerly *Corynebacterium* or *Actinomyces*) *pyogenes* is an ubiquitous organism and is the primary cause of, or a secondary invader in, a wide variety of pyogenic infections in ruminants, pigs and, occasionally, horses. It is present in the environment, in the intestinal tract, and may be carried in the tonsils of healthy cattle. The organism gains access to the body through contaminated abrasions, wounds, or insect bites and the infection may remain localized in the form of a subcutaneous abscess with inflammation of the draining lymph node or it may proceed to *bacteremia* with internal localization. Internal abscessation is frequently clinically silent but is important in food quality. The organism is a cause of *endocarditis* and commonly present in necrotizing pneumonias. It is a common isolate in omphalophlebitis and is also a cause of septic arthritis in calves.

*A. pyogenes* is a common isolate from iatrogenic syndromes such as frontal sinuses following dehorning, injection site abscess, and surgical wound infections. Extensive subcutaneous abscessation and suppurative cellulitis occurs in buller feedlot cattle as a result of multiple skin abrasions.

*A. pyogenes* is a common isolate from intracranial and spinal abscesses, which may result from hematogenous spread, in association with parasitic migration or from invasion from surrounding structures. Outbreaks of spinal abscessation can occur in conjunction with tail-biting in pigs and ear abscessation as a result of ear-biting. A seasonal occurrence of intracranial abscessation occurs in male deer during the period following velvet shedding to the time of antler casting and is associated with wounds and fractures of the antler pedicle. *A. pyogenes* is one of the more common organisms isolated from osteomyelitis in cattle and is also the common isolate from pituitary abscesses.

A syndrome of chronic rhinitis and sinusitis with unilateral or bilateral foul-smelling nasal discharge is reported affecting dairy cattle in three herds in the UK. Contamination of feed by the discharge resulted in feed refusal. There was no evidence of predisposing common respiratory viral or other bacterial infection.

The organism is sensitive to penicillin but infections with *A. pyogenes* are poorly responsive to antimicrobial therapy despite in vitro sensitivity and usually require surgical drainage in combination with antibiotic therapy. Resistance to tetracyclines and tylosin is more prevalent in isolates from animals in which these antimicrobials are used for growth promotion and disease prophylaxis.

**Vaccines** against the organism are commercially available in most countries but there is little evidence that they induce protective immunity against infection or the pyrogenic process.

The role of *A. pyogenes* in the production of *mastitis* in cattle is described in Chapter 15, as a secondary invader in calf and sheep *pneumonia* in the descriptions of the viral pneumonias of calves and sheep, and in *foot abscess* of sheep under that heading.

**Corynebacterium pseudotuberculosis**

*Corynebacterium pseudotuberculosis* is a soil-borne organism and causes caseous lymphadenitis in sheep and goats, ulcerative lymphangitis in cattle and horses, and also external and internal abscesses in horses. The organism possesses a cytoxic surface lipid coat that appears to facilitate intracellular survival and abscess formation and produces a phospholipase exotoxin that increases vascular permeability, has an inhibitory effect on phagocytes, and may facilitate spread of infection in the host. There are two biotypes, with the ovine and caprine isolates a different biotype from equine and cattle isolates.

The important specific diseases associated with *Arcanobacterium*, *Corynebacterium*, and *Actinobaculum* species.
A. pyogenes is an important cause of postpartum metritis and infertility in cattle and sheep. Cows are infected soon after calving and infection is frequently accompanied by infection with the Gram-negative anaerobes *Fusobacterium necrophorum* and *Prevotella melaninogenica* (formerly *Bacteroides melaninogenicus*), which act synergistically, enhancing the growth and pathogenicity of each other. However, the inoculation of pure cultures of *A. pyogenes* into the nonpregnant uterus is followed by the development of endometritis with a persistent corpus luteum. With natural cases, infections are more common after the retention of fetal membranes. Isolation of *A. pyogenes* from the uterus during the postpartum period is significantly associated with endometritis, pyometritis and purulent discharge, resulting in an increase in time to first service, more services to conception, an increase in days open and an increase in cows culled because of infertility. Oxytetracycline is commonly used in therapy but minimum inhibitory concentrations (MICs) of various antibiotics for isolates from the uterus of cattle suggest that cephalosporins would be more effective.

The organism is also a cause of abortion. The fetus is autolyzed but the organism can be isolated from all internal organs and the placenta. Abortion can occur at any stage of pregnancy and has been reproduced experimentally in early pregnancy and in mid-gestation. The prevalence of abortion associated with this organism is low and it accounts for fewer than 5% of abortions in cattle. The examination of a placenta in addition to the aborted fetus improves the accuracy of diagnosis. An unidentified *Corynebacterium*-like organism tentatively identified as *Arcanobacterium pluranimalium* has been isolated from the placenta and stomach contents of lambs in cases of sporadic abortion in sheep.

**PERINATAL DISEASE**

*A. pyogenes* and *Actinobaculum suis* are occasional causes of perinatal sepsis and polyarthritis in calves, lambs, and foals.

**ARTHTRITIS AND BURSITIS**

*Corynebacterium pseudotuberculosis* has been determined to cause a nonsuppurative arthritis and bursitis in lambs. The joints are only slightly enlarged and many animals show only mild clinical signs. Recovery occurs if the lambs are fed and confined.

**PERIODONTAL DISEASE: CARA INCHADA**

*A. pyogenes* and *P. melaninogenica* have been isolated from periodontal lesions occurring in young cattle grazing new pastures sown in recently cleared forest areas in Brazil. The cause of the disease is uncertain and multifactorial but enzymes and toxins from these organisms are stated as being capable of causing primary destruction of periodontal tissue.

Cattle are affected at an age when premolar and molar teeth erupt. Trace element deficiencies have been suspected of predisposing to the disease but are not proven to do so. One theory is that there is a large increase in *Actinomyces* in soil following the clearance of the forest, that these produce antibiotics, mainly streptomycin, and that the ingestion of subinhibitory concentrations of these predisposes to adherence of bacteria to the gingival epithelium. The disease has markedly decreased in incidence in recent years as forest clearing and the occupation of virgin land for cattle raising has almost ceased. Cara inchada is manifest with a purulent periodontitis, halitosis, progressive loss of premolar teeth, mainly of the upper jaw, and emaciation. In risk areas attack rates and case fatality rates are high. The disease can be suppressed by including spiramycin or virginiamycin in the mineral mix fed to the cattle.

**CHRONIC PECTORAL AND VENTRAL MIDLINE ABSCESSES IN HORSES (PIG EON FEVER)**

In California, Texas, and Colorado, *C. pseudotuberculosis* has been associated with a high regional prevalence of chronic abscession in horses. There is no apparent breed or sex predisposition and cases occur in horses of all ages, but the majority are adult horses and there are few cases under 1 year of age. Usually, only a single horse on a farm is affected. A small proportion of farms have endemic infection, with a prevalence of disease of 5–10% and recurrent infections each year. In some years spread to naive horses results in epidemic disease. Cases can occur in all months of the year but are most common in dry months in autumn, with a peak prevalence in September, October, and November. There is a variation in the prevalence from year to year and, in both Texas and California, years with high prevalence of the disease have been preceded by seasons with higher than normal rainfall and conditions that promote high insect populations. Insects, such as horn flies (*Habronema irritans*), that produce a ventral midline dermatitis during feeding may predispose to infection, and the organism has been detected by PCR populations of *H. irritans*, *Stomoxys calcitrans*, and *Musca domestica*. Patterns of spatial and temporal clustering indicate that disease is transmitted directly or indirectly from horse to horse with an incubation period of 3–4 weeks. The disease occurs in a region where caseous lymphadenitis is also common in sheep. Stable hygiene, insect control and isolation of infected horses may aid in control.

**External abscesses**

These occur in a variety of areas on the body but in the majority of cases they are in the pectoral, axillary, inguinal, or ventral midline regions. The abscesses may reach a diameter of 10–20 cm, with a surrounding area of edema, before they rupture 1–4 weeks later. Clinical signs include local swelling, lameness, pain on palpation, ventral edema, reluctance to move, midline dermatitis, fever and depression in the early stage, and eventually rupture of the abscesses.

Treatment of external abscesses is by hot packs to encourage opening and by surgical drainage and lavage. Ultrasound can aid in the detection of deeper abscesses. NSAIDs can be used to control swelling and pain. Recovery rates are excellent and are not improved by antimicrobial therapy.

**Internal abscesses**

These occur at a variety of sites but predominantly in the liver and can occur in horses with no external abscession. The diagnosis should be suspected in horses, in the region and the season, with a clinical history of external abscess, fever, anemia and colic, and laboratory evidence of leukocytosis with neutrophilia, anemia, hyperglobulinemia and hyperfibrinogenemia, and elevated activity of hepatic-associated enzymes. Abdominocentesis in most cases shows an elevated protein and nucleated cell count, and the organism can be cultured. Treatment is with antimicrobial therapy but the case fatality rate is high.

The value of a synergistic hemolysis inhibition serological test in diagnosis has been examined. In horses with external abscesses a range of titers was found but high titers were found in horses with internal abscession. An autogenous vaccine has given protection against experimental challenge but, in field trials, there has been no difference in the incidence of infection between vaccinated and control horses.

*C. pseudotuberculosis* is also recorded as a cause of pericarditis and pleuritis in a
Diseases associated with *Corynebacterium, Actinobaculum, and Arcanobacterium* species

**ETIOLOGY**

*Corynebacterium renale*, the specific etiological agent, has three serotypes of which types I and III appear to be the most pathogenic. Pililated forms occur and may be important in attachment to the epithelium in the reproductive and urinary tract.1,2 *Corynebacterium pilosum* and *Corynebacterium cystitidis* are commonly isolated in conjunction with *C. renale* but are considered part of the normal flora of the vulva.28 *Corynebacterium pseudotuberculosis*, *Arcanobacterium pyogenes*, *Actinobacillus equuli*, *Escherichia coli*, and *Staphylococcus aureus* are sometimes found in the urinary tract of cattle and pigs affected with pyelonephritis, either alone or associated with *C. renale*. Of these organisms, *E. coli* in particular is considered a separate cause of pyelonephritis in the cow.3 *C. renale* has little apparent resistance to physical or chemical agents and can survive in soil for at least 40 days.3 Infection with *C. renale* may stimulate production of antibody that gives cross-reactions with the complement-fixing test for Johne's disease.

**EPIDEMIOLOGY**

**Occurrence**

The disease is widespread in Europe, North America, Australia, Africa, Japan, and Israel and probably occurs in all countries, although it seldom constitutes an important problem in any herd or area.13 As a rule, clinical cases are sporadic, even in herds found to harbor a significant number of carriers. Differences in disease prevalence probably reflect differences in management. One study in seven herds found an annual incidence that varied from 0.5–1.5% and in one herd was 16%.6 Subclinical infection may be more frequent than commonly recognized. Chronic cystitis and pyelonephritis (etiology unestablished) have been found in 5.3% and 0.2% of cattle at slaughter.5,6 Although pyelonephritis is considered to be essentially a bovine disease, sheep are occasionally affected.

**Source of infection and transmission**

*C. renale* can be isolated from the urine of affected or carrier animals and in Japan has been isolated from the vagina or vaginal vestibule of approximately 6% of healthy cows.3 The incidence of cows excreting *C. renale* in their urine is higher in herds where the disease occurs than in herds where the disease is unknown. *C. renale* is present in the urinary tract of other animals, including rodents, and can be isolated from dust and the environment of infected animals.7

In cattle, infection can be transmitted by direct contact, by the use of contaminated brushes or by the careless use of catheters. A change in the policy of catheterizing cows with suspect ketosis for the collection of urine can be associated with a fall in the incidence of the disease.

There is a strong inference that in some circumstances the disease, or the infection, can be spread venereally. This is suggested by the occasional occurrence of a series of cases in a herd, usually related to the use of a particular bull,8 and the cessation of cases when artificial insemination is used. The organism can often be isolated from the prepuce, urethra, and semen of bulls that have no detectable lesions in the prepuce. *C. renale* can be a cause of balanoposthitis in bulls.

**Risk factors**

Cattle are seldom affected before maturity and cows appear to be much more susceptible than bulls. In cows, clinical cases are more common in early lactation. *Mature cows* of all ages are susceptible but in one study there was a significantly higher risk for disease in cows in their second lactation.4 An increase in clinical cases is usually found in the colder seasons of the year and heavily fed, high-producing dairy herds appear to show an increased susceptibility.

A significant decreased risk for pyelonephritis has been found for cows that have postparturient uterine disease, which may be associated with the treatment of these cows with antibiotics.7

Bulls can be predisposed to pyelonephritis by obstructive urinary abnormalities.9

In Israel, the ingestion of rock rose (*Cistus salvifolius*) is reported to produce urinary retention and predisposes to pyelonephritis.10

**Experimental production**

The disease can be reproduced by inoculation of the organism into the urethra.11,12 It can also be reproduced by intravenous challenge, although the vulva is believed to be the natural portal of entry. Although not intentionally produced, the disease occurred in 10% of a group of cattle used to teach veterinary students the technique of urinary catheterization.

**Economic importance**

Unless appropriate treatment is instituted early, the disease is highly fatal and economic loss is due mainly to the deaths of affected animals.

**PATHOGENESIS**

Pyelonephritis usually develops as an ascending infection involving successively the bladder, ureters, and kidneys. Trauma to the urethra, or urine stasis, may facilitate ascending infection. The destruction of renal tissue and obstruction of urinary outflow ultimately result in uremia and the death of the animal.

Piliated and nonpiliated forms of *C. renale* are present in infected animals but...
The course is usually several weeks or even months and the terminal signs are those of uremia.

**CLINICAL PATHOLOGY**

There is proteinuria and hematuria. Urine pH is greater than 8.5 and the specific gravity has been recorded between 1.008 and 1.021. Microscopic examination will show pyuria. The presence of C. renale in suspected urine can be confirmed by culture, specific immunofluorescence or direct microscopic examination.

There may be hypoalbuminemia and hypergammaglobulinemia. Neutrophilia may be present but is not constant in all cases. There is an elevation of serum creatinine and urea, and concentrations above 1.5 mg/dL and 100 mg/dL, respectively, carry a grave prognosis.

Renal biopsy and ultrasound can aid in diagnosis. Ultrasound may demonstrate a dilated renal collecting system containing echogenic material and can be an aid in the determination of the severity of the disease.

**NECROPSY FINDINGS**

The kidneys are usually enlarged and the lobulation less evident than normal. The renal calyces and grossly enlarged ureters contain blood, pus, and mucus. Light-colored necrotic areas may be observed on the kidney surface. Changes visible on the cut surface include excava­tion of papillae, abscessation and wedge-shaped areas of necrosis that extend from the distal medulla into the cortex. The bladder and urethra are thick-walled and their mucous membranes are hemorrhagic, edematous and eroded. Histologically, the renal lesions are a confusing mixture of acute supplicative changes and various degrees of fibrosis with mononuclear cell infiltration.

**Samples for confirmation of diagnosis**

- Bacteriology – kidney; culture swab from ureter (CULT)
- Histology – formalin-fixed kidney, ureter, bladder (LM)
- Clinical pathology – 1 mL aqueous fluid from eye (BUN).

**TREATMENT**

Although several antibiotics appear to inhibit C. renale, penicillin remains the antibiotic of choice for treatment of pyelonephritis. Large doses (15,000 IU/kg BW of procaine penicillin G) are recommended daily for at least 3 weeks. In early cases where little structural damage has occurred, permanent recovery can be expected following such a course of treatment. In general, a good prognosis is suggested by an improvement in condition, appetite and milk yield and clearing of the urine. However, in well-established cases, relapse is not uncommon and, where tissue destruction has been extensive, relief through antibiotic therapy is only temporary. In valuable animals, where ultrasound has established the diagnosis, unilateral nephrectomy may be an alternative and the surgical technique has been described.

**CONTROL**

No specific control measures are usually practiced but isolation of affected animals and destruction of infected litter and bedding should reduce the population of the organism in the local environment and minimize the opportunity for transmission. Procedures such as urinary catheterization should be avoided and routine vaginal examinations should be conducted with proper hygiene precautions. Where natural breeding is practiced, some reduction in occurrence may be achieved by the introduction of artificial insemination.

**REFERENCES**

CYSTITIS AND PYELONEPHRITIS OF SOWS

Etiology
Actinobaculum suis
(Eubacterium suis, Corynebacterium suis) is the specific cause but a range of other bacteria (principally Escherichia coli) may also cause the condition.

Epidemiology
Infection of male pigs causes the disease in sows. Organism is in the prepuse and environment. Transmission is venereal and through dirty farrowing houses. Trauma to the urogenital tract of females predisposes to disease.

Clinical findings
Unexpected death in acute cases. Pain on urination, bloodstained, turbid urine accompanied by vaginal discharge. Cystitis on endoscopic examination.

Clinical patholgy
Hematuria, pyuria, proteinuria, bacteremia. Urine pH > 8.5. Demonstration of organism by culture or immunofluorescence. Azotemia, increased concentrations of urea and creatinine, hyperkalemia and hyponatremia.

Necropsy findings
Purulent cystitis and pyelonephritis.

Diagnostic confirmation
Urinalysis, endoscopic examination and demonstration of A. suis.

Treatment
Unrewarding unless early in the course of the disease – antimicrobials and supportive therapy. Humane destruction of cases.

Control
Antimicrobials by injection, in water or in feed. Insure adequate water supply for lactating sows to aid urination and improve postfarrowing hygiene.

ETIOLOGY
The disease is associated with a variety of agents. A variety of syndromes associated with different bacteria can be distinguished.

Urinary tract infections in sows can be associated with E. coli and other bacteria (Pseudomonas aeruginosa, staphylococi, streptococi, Proteus spp., Klebsiella spp., enterococi, and A. pyogenes) and infections with most of these organisms result in catarhali/purulent cystitis.

The specific disease is most commonly associated with Actinobaculum suis. This was formerly known as Eubacterium suis before that as Corynebacterium suis. This organism is a Gram-positive rod that is difficult and slow to grow and requires special culture media.

All these organisms causing this problem are believed to produce the condition as a result of ascending infection. The disease is a particular problem when sows are in stalls or tethered. The condition may not be so serious when associated with all the species other than A. suis and in these cases may be seen as frequent urination, the presence of blood or pus in the urine and a progressive loss of condition.

EPIDEMIOLOGY
The disease occurs in postpubertal sows that have bred.

Occurrence
The infection may be common but the disease is better viewed as sporadic.

The disease is probably worldwide and has been reported from Great Britain, Europe, North America, Asia, and Australia. It occurs both in outdoor and indoor units. There are no measures of prevalence, although it has been described as the most important cause of sow deaths, with up to 25% associated with urinary tract infection. It probably occurs more frequently than is recognized as there is a considerable subclinical infection rate. In a recent study in the USA, A. suis was isolated from 4.7% of the bladders of sows collected at random at a slaughterhouse.

In small herds, the disease tends to occur in small outbreaks when a small number of sows become infected after being mated to a single boar. Often, the clinical outbreak may be 2-3 weeks after the use of the suspected boar. More serious outbreaks can occur in large intensive piggeries. The disease can also occur sporadically and be a normal feature of sow mortality.

In a recent study of 1745 pregnant sows 28.3% were found to have urinary infections and A. suis was found in 20.6% of these. A. suis was less prevalent (13.7%) in the sows with urinary infections than in those without (23.1%). In an abattoir survey in the Netherlands the prevalence of cystitis in slaughtered sows was 11%, with a variation depending on group from 0-35%. In this study of 114 bladders, A. suis was not isolated but E. coli was the most commonly isolated together with S. dysgalactiae, A. pyogenes, Aerococcus viridans, and S. suis.

Source of infection and transmission
A. suis is a normal inhabitant of the porcine prepuce and can be isolated from the preputial diverticulum of boars of various ages. The prevalence of the infection in adult males may be as high as 90% and the organism can be isolated from the floor of the penis containing infected boars.

Infection and colonization of the preputial diverticulum may occur in pigs as early as 5 weeks of age if they are housed with older pigs. Frequently, this infection may occur from pen floor contamination because of poor hygiene. Piglets can also become infected, at an early age, from sows that have chronic cystitis and pyelonephritis, and the infection can spread rapidly to other male pigs when they are grouped at weaning. Although infection is common in the male pig, cystitis and pyelonephritis is extremely uncommon in males. A. suis is rarely isolated from the urogenital tract of the healthy female pig.

Clinical disease is almost entirely restricted to the female pig that has bred.

Venereal transmission is believed to be the primary if not the sole method of infection of the sow.

Trauma to the vagina may be an important predisposing factor allowing infection to establish and trauma at parturition with infection from the environment may also be important.

There is no doubt that, where the conditions in stall houses are bad with fecal contamination and poor drainage from the rear half of the stall, perineal and vulval contamination is much greater.

Risk factors
Clinical signs may occur at any age but are common at 3-4 weeks post-service. The disease is more common in sows kept in intensive confinement conditions than in those that are kept in open lots, pens, or pasture but it does occur in these systems if the hygiene is poor. Differences in feeding patterns and exercise that occur in the different management systems can influence the frequency and volume of water intake. This in turn has an important effect on the frequency of urination and the residual volume of urine in the bladder following micturition, which is one of the factors that may predispose to the establishment of urinary tract infection.

Since many lactating sows will only stand when they are fed, usually twice a day, they will also only urinate and drink twice a day. If they cannot take in enough water from either a trough or a tap during this period at the correct flow rate, they may be suffering from an inadequate water intake. It has also been shown that crystalluria may well damage the mucosa and aid the formation of cystitis and that the crystals also support infection of the bladder, particularly where there is an insufficient water supply.

Economic importance
In one of the best studies of sow mortality in the UK it was reported that the principal cause of death in up to 25% of the sows was urinary tract infection. If the sow mortality is below 5% then cystitis/pyelonephritis is unlikely to be an important problem in the herd.

Cystitis and pyelonephritis is of great importance as it is a major cause of death (annual death rate may be in excess of 5% in sows in both Britain and the USA and even more importantly a cause of serious culling as the recommendation is to cull affected sows as they will always be a source of infection. Considerable prevention, treatment and hygiene costs will also ensue.
PATHOGENESIS
In healthy sows A. suis can be isolated from the vagina, but not from the bladder, for a short period after an infected service. The factors that allow it to establish in the urogenital tract are unknown but trauma to the vagina and urethral opening and service into the bladder are supposed factors. It has been suggested that the other organisms mentioned above may also act synergistically to damage the mucosa and facilitate colonization by A. suis. This may be true, as A. suis possesses pili by which it attaches to damaged bladder epithelium. Cystitis results in damage to the ureterovesiculaL junction and there is an ascending infection from the bladder to the kidneys. In infected sows, tortuosity of the ureters and blockage of the ureters is fairly common. This and the changes in the kidney may lead to chronic renal failure and even acute renal failure if the blockage is complete and bilateral.

CLINICAL FINDINGS
It is worth remembering that many mildly affected sows may only show transient inappetence, and other animals are recognized because they are uremic. In the more severely affected groups the presentation is either as an acute case, usually postpartum sows and above. They are frequently febrile with the longest interval 5 days. In a recent study in Ireland the authors reported the condition mainly in fourth parity sows and above.

Where the surveillance is good the sows are observed to be dehydrated, anorectic, mildly febrile (normal to 39.5°C, 103°F) and sometimes show arching of the back, swelling of the tail and painful urination. There is frequent passage of bloodstained, turbid urine accompanied by vaginal discharge. Examination with a vaginal speculum will confirm the bladder as the source of the bloody discharge. The case fatality rate is high. Sows that survive the acute disease develop chronic renal failure with weight loss and polydipsia and polyuria. They are usually culled for poor performance.

Endoscopic examination of the bladder in acute cases may show little other than mild inflammation but in more serious cases there are ulcerative and erosive bladder lesions. In sows large enough to allow rectal examination, in chronic cases it may be possible to feel the large and thickened bladder and dilated tortuous ureters. Boars are usually unaffected clinically but intermittent, hematuric episodes lasting several days have been recorded.

The condition can be seen as a sequel to any locomotory, particularly central brain or spinal condition in which there is an inability to stand to drink or micturate, e.g. organophosphorus poisoning.

CLINICAL PATHOLOGY
Sows' urine is frequently turbid (83.1%) and usually this can be associated with the presence of crystals (96.1%). Urinalysis usually shows hematuria, pyuria, proteinuria, and a pronounced bacteriuria (usually in excess of 10^5 cfu/mL of urine). A Gram stain on a smear of the urine or pus may show the organisms. The urine is alkaline with a pH of more than 8.5 and usually approaching 9 as a result of the urease, which cleaves urea to produce ammonia. Midstream urine contains 10^5 cfu/mL or more. A number of species of bacteria may be found as suggested in the introduction but A. suis requires special culture media. It is now possible to use immunofluorescence for more rapid and specific diagnosis. Examination of blood shows a pronounced azotemia, with increased concentrations of urea and creatinine and also hyperkalemia and hyponatremia. N-acetyl-B-D-glucosaminidase concentrations are elevated, indicating proximal renal tubular damage.

NECROPSY FINDINGS
A very varied pathology may be visible in these cases. In some sows there may be an extensive purulent nephritis and pyelitis with similar changes in the dilated ureters and the bladder. In others there may be severely hemorrhagic kidneys and blood in the pelvices.

In acute cases the bladder wall is swollen, edematous, and hyperemic and may be covered by a gritty, mucinous material. In others the bladder wall may be thickened, inflamed and covered by an extensive thick mucus. In some of these cases the ureterovesicular valves may have been completely destroyed by necrosis. There may be minimal gross changes in the kidneys in acute cases but there may be microscopic changes of a diffuse tubular and interstitial nephritis. In the chronic case there are ulcerative and erosive lesions in the bladder wall and there may be pus in the bladder, thick-walled ureters and an obvious pyelonephritis.

Samples for the confirmation of diagnosis
- Bacteriology – kidney, bladder, and ureter for aerobic and anaerobic culture and special media for A. suis.
- A special urea-enriched medium in which dry colonies of A. suis, about 2–3 mm in diameter, grow after 2 days incubation.
- Histology – formalin-fixed bladder, ureter, and kidney
- Clinical pathology – from the eye (BUN).

DIAGNOSIS
Diagnosis is based on high mortality, clinical findings, history of service, clinical pathology, particularly bacteriology, immunofluorescence for specific bacteria, or isolation by culture.

DIFFERENTIAL DIAGNOSIS
- Other causes of sudden and unexpected deaths
- Hematuria
- Staphylococcus denstus (where it occurs)
- The separation of the condition associated with A. suis from those associated with other bacteria can only be achieved by bacterial culture and other laboratory techniques.

TREATMENT
Early treatment with antibiotics is recommended, but if there is acute renal failure then the case fatality rate is high. Penicillin given at 15 000 IU/kg daily for 3–5 days has been successful. The intramuscular injection of streptomycin at 10 mg/kg has also been used successfully. The isolation of other organisms may indicate the need for other broad-spectrum antibiotics. A recent outbreak of cystitis and endometritis was associated with a falling conception rate from 88% to 75% and believed to be due to E. coli (together with staphylococci and streptococci) was successfully treated with an ammonium chloride urinary acidifier whereas the amoxicillin used previously was without effect. Enrofloxacin at the rate of 10 mg/kg BW in the feed for a period of 10 days has also proved effective, as has 2.5 mg/kg in the food for at least 20 days.

The response can be monitored by the reduction in the urine pH. Treated sows should be loose housed with access to plenty of water. The treatment should be continued for at least 2–3 weeks after the outbreak has appeared to finish clinically. Oral electrolyte therapy is also beneficial. In chronic cases the lesions are well advanced and the organisms may be contained in the calculi and then therapy is not successful and relapses may well occur. In many cases humane destruction
by urease-producing organisms present in the prepuce and vagina. Estrogens in pasture, causing swelling and congestion of the prepuce, may predispose to disease. Most commonly the organism is *C. renale* but an outbreak of posthitis in sheep associated with *Rhodococcus equi* and *Corynebacterium hofmannii*, both of which produce urease, and not associated with *C. renale*, is described.¹

*Mycoplasma mycoides* LC has also been incriminated as a cause of posthitis and vulvovaginitis in sheep.²

**EPILEDIOLOGY**

The disease is reported primarily from Australia, South Africa, and South America but occurs in all countries with large pastoral sheep industries.

**Host occurrence**

Sheep

In Australia, enzootic posthitis occurs most commonly in Merino sheep, particularly wethers over 3 years of age and young rams, but in a severe outbreak young wethers and old rams may also be affected. An ulcerative *vulvitis* often occurs in ewes in the same flocks in which posthitis occurs in wethers and is thought to be a venereal extension of that disease. The disease also occurs in goats.³

Cattle

Posthitis is uncommon in bulls but is reported to occur at high rates and to be economically important in South America.⁴ There appears to be no counterpart to ovine vulvitis in cows.

**Source of infection and transmission**

The causative organism can be recovered from lesions and from the clinically normal prepuce of most sheep. It is also present in the lesions of vulvitis in ewes and posthitis in bulls and Angora goat wethers.

Flies are considered to be probable mechanical vectors, and contact with infected soil and herbage is a likely method of spread. Infection at dipping or shearing appears to occur venereally from infected rams. Although the natural disease in cattle is usually benign they may act as reservoirs of infection for sheep on the same farm.

**Host and environmental risk factors**

**Diet and season**

The major risk factors.

is the best option especially as it is not possible except in very early cases to eliminate the organism. Preputial washing on a regular basis may prevent the carriage of organisms by boars especially as it has been shown that semen may be frequently contaminated by *A. suis*, and it is said that up to 50% of boars in some studs may be affected.

**CONTROL**

Routine prophylactic administration of antibiotics has proved of little value in the long-term control of the disease. A temporary solution has been the use of sow treatment with oxytetracycline followed by in-feed medication with 400 g/ton for 21 days.¹¹ It is not possible to eradicate the infection from the prepuce of a boar, although daily infusions may help to reduce the infection.⁶ Artificial insemination with the semen treated with antibiotics is a further option.

**Trauma**

To the vagina at mating should be reduced by boar management and the supervision of mating. There should be nonslip floors in the service areas. Animals showing distress, pain, or bleeding after mating should be treated.

The service areas should have very good hygiene with regular cleaning and disinfection after use. The perineal region of each sow should be cleaned before mating. Farrowing accommodation and crates should also be properly cleaned and disinfected and allowed to dry before sows are introduced. The major organism (*A. suis*) will persist in bad floors but is susceptible to phenolic, quaternary amonium and formalin-based products.⁹

Other control procedures involve the provision of an adequate water intake. This should preferably be from the mains without impurities or toxins or bacterial contamination. Loose housing and twice-daily feeding will encourage the consumption of water. The provision of adequate numbers of drinkers for the necessary flow rate for each age of pig is essential (at least 1.5 L/min for gestating sows and 2.2 L/min for lactating sows). A simple check on water supply can be to check appetite: if the sows are not consuming 10 kg of food on day 18 of lactation then there is probably something wrong with water provision. Similarly, troughs must contain at least a reasonable supply of water. In the welfare codes all animals have to be provided with a fresh supply of high quality water.

the disease is so common that it is not possible to maintain bands of wethers.

Factors of lesser importance are continued wetness of the area around the prepuce due to removal of preputial hairs at shearing, a high-calcium, low-phosphorus diet and the ingestion of large quantities of alkaline water.

The high incidence in castrates and young rams is probably related to the close adherence of the preputial and penile skins, which separate in mature entire animals, and to a lesser understood influence of testosterone.

Experimental reproduction
Implantation of the organism on a scarified prepuce in the presence of urine is capable of causing the external ulceration that is characteristic of the disease.

Economic importance
Many deaths occur because of uremia and secondary bacterial infections and all affected sheep show a severe setback in growth rate and wool production. Young rams that are affected are incapable of mating.

PATHOGENESIS
The organism is capable of hydrolyzing urea with the production of ammonia. It is believed the initial lesion in the wether (the external lesion) is caused by the cytoxic effect of ammonia, produced from urea in the urine by the causative bacteria. This lesion may remain in a static condition for a long period but, when there is a high urea content of the urine associated with a high-protein diet, and continued wetting of the wool around the prepuce, the lesion proceeds to invade the interior of the prepuce, producing the ‘internal lesion’. A similar pathogenesis is postulated for vulvar lesions.

CLINICAL PATHOLOGY
Isolation of the causative diphtheroid bacterium may be necessary if there is doubt as to the identity of the disease.

NECROPSY AND DIAGNOSTIC CONFIRMATION
Necropsy is not required and the diagnosis is clinical.

DIFERENTIAL DIAGNOSIS
- Ulcerative dermatosis in sheep
- Herpes balanoposthitis in bulls

Obstructive urolithiasis in wethers may superficially resemble posthitis but there is no preputial lesion.

TREATMENT
The principal measures are restriction of the diet to reduce the urca content of the urine, removal of the wool around the prepuce or vulva to reduce the risk of fly strike, segregation of affected sheep and disinfection of the preputial area, and surgical treatment of severe cases.

Sheep can be removed on to dry pasture and their feed intake restricted to that required for subsistence only. They should be inspected at regular intervals, the wool should be shaved from around the prepuce, and affected animals should be treated individually. Weekly application of a 10% copper sulfate ointment is recommended for external lesions; when the interior of the prepuce is involved, it should be irrigated twice weekly with a 5% solution of copper sulfate. Cetrimide (20% in alcohol or water or with or without 0.25% acid fuchsin) or alcohol alone (90%) are about as effective as copper sulfate preparations.

Penicillin topically or parenterally may effect a temporary response. Thiabendazole by mouth appears to have a beneficial effect on the lesions but does not eliminate them.

In severe cases the only satisfactory treatment is surgical, and surgical treatment is necessary if the prepuce is obstructed. The recommended procedure is to open the ventral sheath by inserting one blade of a pair of scissors into the external preputial orifice and cutting the prepuce back as far as the end of the urethral process; extension beyond this leads to trauma of the penis. Badly affected rams should be disposed of as they are unlikely to be of value for breeding.

CONTROL
Subcutaneous implantation with testosterone propionate is highly effective as a preventive but is no longer used for sheep that will be used for human food. A single implantation of 60–90 mg is effective for 3 months; although the treatments can be repeated four times a year, it is more economical to time them to coincide with periods of maximum incidence, which will vary from district to district. Three implantations in fall, winter, and spring provide an effective control program in most areas. The tablets are implanted subcutaneously, preferably at the base of the ear, using preloaded tubes to avoid undue contact to the operator.

Alternative control procedures are under investigation, in part because of public resistance to meat products exposed to synthetic hormones. One alternative is to run male lambs as cryptorchids, so-called short scrotum lambs. The testes are pushed into the inguinal canal and a rubber ring is applied to remove the scrotum. Another is to run male lambs as hemicastrates. The prevalence of posthitis is significantly reduced in Merino short scrotum lambs and hemicastrates. There is an increase in live weight, with no increase in fleece weight, but there are obvious masculine characteristics such as horn growth.

**ETIOLOGY**

*Corynebacterium pseudotuberculosis* is the specific cause of the disease. There are two proposed biotypes, ovine/caprine and equine/bovine. Both biotypes produce an exotoxin, phospholipase D, which functions as a sphingomyelinase and is an immunodominant antigen. Variation in toxin production between strains may be related to differences in pathogenicity. The toxic lipid cell wall mediates resistance to killing by phagocytes and is also a virulence factor.

*C. pseudotuberculosis* is also the cause of ulcerative lymphangitis of cattle and horses, and contagious acne of horses, but these have been dealt with as separate diseases because they appear to have a separate pathogenesis and do not occur in association with caseous lymphadenitis.

**EPIDEMIOLOGY**

**Geographical occurrence** Caseous lymphadenitis occurs in the major sheep-producing countries in the world including Australia, New Zealand, South Africa, the Middle East, North and South America, the UK, and most of northern and southern Europe. The disease did not occur in the UK and the Netherlands until the importation of infected goats in the late 1980s but subsequently spread to be an important disease in both countries.

**Host occurrence** Caseous lymphadenitis occurs in sheep and goats.

Sheep

Caseous lymphadenitis increases in prevalence with age and reaches a peak incidence in adults. In one Australian population of unvaccinated sheep the frequency of infection at abattoir inspection was 3.4% for lambs and 54% for adult ewes and similar levels of prevalence are recorded in North America and South America.

In another large study of mature age slaughter sheep in Australia the overall prevalence of lesions was 26%, with carcass lesions in 20.4% of sheep and offal lesions in 9.5%. The prevalence of lesioned sheep from individual farms can be higher. The prevalence of infection in ewes culled for age in Western Australia has fallen from over 50% in the 1980s to approximately 25% in the early 2000s, which is suggested to be in part the result of the cessation of compulsory dipping for lice during this period.

Following the introduction to British flocks in the late 1980s, outbreaks increased to reach a peak in 1998 and have decreased in occurrence since. An examination, by pulse field gel electrophoresis, of isolates through this period suggests that all are related to the initial introduction.

A recent serological survey of 745 flocks showed an overall prevalence of seropositive animals of approximately 10%, with 18% of the flocks sampled having one or more positive animals.

**Goats**

Prevalence rates in goats may be lower than in sheep. In *domesticated* goats an overall prevalence rate of 8% is recorded in the USA and a similar prevalence is recorded in *feral* goats in Australia. As with sheep the prevalence increases with age – the prevalence at 4 years of age is as high as 22%. The assessment of prevalence in goats based on the presence of abscess is complicated by the fact that a significant proportion of abscesses in goats may be produced by *Arcanobacterium pyogenes*.

**Source of infection**

The primary habitat of *C. pseudotuberculosis* is in infected animals. Sources of infection are the discharges from ruptured abscessed superficial lymph nodes and the nasal and oral secretions from animals with pulmonary abscesses draining into the bronchial tree.

The organism can survive in pus-infected soil for up to 8 months, in infected shearing sheds for approximately 4 months, and on straw, hay and other forimtes for up to 2 months, but it is not easily isolated from the soil of infected premises.

Low temperatures and moist conditions prolong survival time. Infectivity persists in sheep dips for at least 24 hours.

**Transmission**

Infection of an animal is facilitated by the presence of skin wounds but the organism can invade through intact skin. Transmission is by direct contact with infective discharges or mediated by contaminated shearing equipment, contaminated shearing shed boards or holding pens, contaminated dipping or shower fluids, or dust from contaminated shearing sheds and yards.

**Risk factors**

**Sheep**

Most studies on risk factors have been conducted in Australia and observed risk factors may not always apply to management systems in other countries.

**Age and sex**

There is a higher prevalence in older sheep, which probably reflects greater exposure to risk factors such as shearing. In the UK a disproportionate number of rams are infected and there is a significant prevalence of infection in terminal sire breeds, which are an important vector to other closed flocks. The prevalence in rams may be related to the high stocking rate at which rams are kept for most of the year and fighting behavior with transmission through head wounds.

**Breed**

All breeds are susceptible but, in New Zealand, which has a mix of fine wool and meat sheep breeds, the prevalence of disease is higher in Merino and Merino-cross breeds. This may relate to greater susceptibility to skin damage at shearing because of their finer skin and the presence of neck wrinkles. In the UK, infection is more prevalent in terminal sire breeds.

**Shearing**

Shearing is a major risk factor in sheep and, in general, infection rates increase with the number of times sheep have been shorn. The risk for spread varies with shearing. When spread occurs, it occurs mostly within groups of sheep shorn together. Sheep may be infected by transfer of pus from abscesses discharging or cut at shearing, via shearing combs, but spread from sheep with discharging pulmonary abscesses to sheep with skin cuts is considered more important.

**Close contact** of recently shorn sheep in any circumstance may facilitate transmission of the disease through the contact of infected respiratory secretions with susceptible skin. Sheep are commonly in close contact in collecting pens immediately following shearing and infected nasal and oral secretions can be deposited...
directly on to shearing cuts. Keeping sheep under cover for more than an hour after shearing increases the odds for spread. Poor hygiene in the shearing shed, allowing contamination of shearing boards and holding pens, may allow infection of sheep. Movement of infection between flocks can occur through contamination of shearing equipment, of mobile shearing sheds and infection on the clothing of shearsers. Contact shearing has been shown to be a risk factor in the UK. Dust from contaminated yards may transmit infection to recently sheared sheep, although epidemiological studies suggest that environmental contamination is not a major risk factor for disease in Australia. Housing Close contact associated with high stock- ing rates at pasture or in-door housing for much of the year may lead to high rates of infection. The difference in lesion distribution between sheep in the UK and Australia is believed to be due to close contact at shared feed troughs under conditions of intensive husbandry in the UK. Dips The organism can persist in reused (plunge dip) or recycled (shower dip) fluids used for ectoparasite control. As few as 25 organisms/mL in the dip can produce infection. Sheep dipped in infected dipping fluid within a few days of having been shorn are especially susceptible to infection because of the ease of contact between the bacteria and the skin but spread can also occur through dips in sheep shorn 6 months previously. An experimental study, where infection-free sheep were shorn and exposed to artificially contaminated dips at 0, 2, 4, 8, and 24 weeks after shearing, showed that a larger percentage of the sheep dipped immediately after shearing seroconverted and had lymph node lesions at slaughter. However, lesions also were present at slaughter in sheep dipped 2 or more weeks after shearing and there was no significant difference in their prevalence in the groups dipped at 2-24 weeks after shearing. This supports the observation that infection can occur through intact skin, possibly in the case of dip-associated infections, influenced by loss of wool grease because of wetting agents in the dip. Shower dipping sheep immediately after shearing also significantly increases the odds of a high incidence of caseous lymphadenitis. Whereas shearing and dipping are important risk factors, disease can also be transmitted from sheep with pulmonary abscesses to nonshorn sheep by contact. Goats Shearing is not a risk factor, other than with Angoras. The difference in abscess distribution in goats compared to sheep, with a predominance in the head, neck and sternum in goats, suggests that contact, fomites and trauma are important vector mechanisms. Social contact, head butting, trauma from browse and the use of common neck collars and feed troughs are probable risk factors. Pulmonary abscesses are not as prevalent in goats as in sheep and may be of lesser importance as a source of infection. With both sheep and goats, contamination of soil on bedding grounds, in yards, or in shelters may result in persistence of the organism in the environment for periods significant to the transmission of the disease and can result in infection of wounds created by docking and castration and infection in the region of the sternum. Experimental reproduction The disease can be readily produced experimentally in sheep and goats by parenteral or intradermal injection, and in both species abscesses form in regional draining lymph nodes and in internal organs. The disease can also be produced experimentally in sheep by exposure to contaminated dips. The incubation period for the development and rupture of abscesses in regional lymph nodes varies from 3 weeks to 6 months, and shedding of C. pseudotuberculosis from open abscesses averages 20 days. Economic importance In the majority of young infected animals there is no overt clinical disease or impairment of health other than visible abscessation but the disease is of considerable economic importance to the sheep and goat industries. In sheep, infection has been associated with a 6.6% reduction in clean fleece weight in the first year of infection and a reduction in growth rate. Infection is a significant cause of condemnation of carcass for human consumption with condemnation rates as high as 3–5% for mutton carcasses and 0.02–0.03% for lamb carcasses. Condemnation rates and economic loss varies depending on country – differences in the number of abscessed lymph nodes dictating condemnation rather than carcass trimming. In goats the hide can represent a significant proportion of the value of the carcass and blemishes produced by infection markedly reduce its value. Clinical disease occurs in animals with the disseminated visceral form which is a cause of reproductive inefficiency, a major cause of the thin ewe syndrome, and of death and culling in older sheep in infected flocks. Zoonotic implications Human infection is rare, produces a lymphadenitis with a long and recurrent course and is an occupational disease of shearsers and abattoir workers with infection occurring through cuts. C. pseudotuberculosis may be present in the milk of goats from udders where the mammary lymph node is affected. PATHOGENESIS Multiple microscopic abscesses develop in the draining lymph node by 1 day after experimental infection in the skin, and between 3 and 10 days of infection these coalesce to form typical pyogranulomas. The siphingomyelin-specific phospholipase D exotoxin produced by the organism is believed to facilitate spread of infection by promoting leakage of plasma from small blood vessels at the site of infection with flooding of lymphatic spaces. Abscesses develop in 60–80% of infected sheep. The high lipid content of the bacterial cell wall gives resistance to the digestive enzymes of the phagocyte and the organism persists as a facultative intracellular parasite. The reduction of wool growth in the first year of infection probably results from the catabolic effects of cytokine and toxic metabolites released during the acute inflammatory and immune response to initial infection. Hematogenous spread of the organism results in abscess formation in many organs and these may occur in the absence of peripheral lesions. Up to 25% of affected sheep at abattoirs are recorded as having lesions only in thoracic viscera. This tendency for a high incidence of lesions in the lung appears to be general, but prevalence varies considerably between geographical areas. The abdominal visceral and somatic tissues are also commonly affected. Less commonly, hematogenous infection occurs in young lambs to produce septicemic disease. CLINICAL FINDINGS There is palpable enlargement of one or more of the superficial lymph nodes. Those most commonly affected are the submaxillary, prescapular, prefemoral, supramammary and popliteal nodes. The abscesses commonly rupture and creamy to caseated pus, with no odor, is di-charged. Goats have a much greater proportion of lesions in the lymph nodes draining the head, related possibly to superficial injury during browsing. Abscesses may subsequently develop in other lymph nodes. In the UK, clinical signs of infection in sheep are most commonly associated with the superficial lymph nodes of the head and neck. Both sheep and goats may also show abscess in
the skin, particularly of the face, with loss of overlying hair.

In cases in which systemic involvement occurs, chronic pneumonia, pyelonephritis, ataxia, and paraplegia may be present depending on the site of infection. The debilitating disease of adult ewes commonly referred to as 'thin ewe syndrome' is often associated with the occurrence of internal abscesses (81% of ewes), many of which contain C. pseudotuberculosis (86%). Other bacteria, especially Moraxella spp., are also commonly present. In ewes, local spread from the supramammary lymph node to the mammary tissue is common. The resulting fall in milk yields leads to poor growth and even death of lambs and this may be a serious economic feature in badly affected flocks. Intracranial lesions are common in rams but do not involve the testicles or semen.

CLINICAL PATHOLOGY

There is an increase in blood lymphocytes and neutrophils. C. pseudotuberculosis can be cultured from pus obtained by needle biopsy or by transtracheal wash.

Serological tests that have been used in serodiagnosis include indirect hemagglutination, hemolysis inhibition, synergic hemolysis inhibition, immunodiffusion and ELISA tests to detect antibody to cell wall antigens or to the phospholipase exoenzyme. Many of these tests have good specificity but few have high specificity and sensitivity. Some have been used to determine flock infection and have been used in eradication schemes. As yet, none is sufficiently reliable to confidently detect infection in individual sheep. The sensitivity of equivalent tests in goats is generally higher and they are used for official control schemes in goats in some countries. An indirect double antibody sandwich ELISA with high specificity and sensitivity at the herd level in goats and sheep is being used in herd eradication of caseous lymphadenitis in the Netherlands.

Recently, an interferon-gamma assay that assesses cell-mediated immunity rather than humoral immunity has been developed and showed high reliability in detecting both infected and noninfected sheep and goats in a limited number of experimental animals.

NECROPSY FINDINGS

Caseous abscesses filled with greenish-yellow pus occur chiefly in lymph nodes and to a lesser extent in internal organs. In the early stages the pus is soft and pasty but in the later stages it is firm and dry and has a characteristic lamellated appearance. Locally extensive broncho-pneumonia, with more fluid pus of a similar color, may also be present. Microscopically, nodal architecture is effaced by the abscess. As the lesion expands, the limiting fibrous wall keeps reforming, creating the 'onion-skin' layering noted grossly.

Samples for confirmation of diagnosis
- Bacteriology – lymph node, lung, culture swab from outer portion of abscess (CULT)
- Histology – formalin-fixed lymph node (LM).

DIFFERENTIAL DIAGNOSIS

- Melioidosis
- Tularemia
- Other causes of pneumonia in small ruminants
- Lymphosarcoma (rare)

Suppurative lymphadenitis in lambs has also been found to be associated with infection with Pasteurella multocida, and a disease characterized by the presence of yellow-green pus in abscesses situated in close proximity to the lymph nodes of sheep is associated with a Gram-positive micrococci. The latter disease occurs in France and Kenya and is referred to as Morel's disease.

TREATMENT

The organism is susceptible to antibiotics other than the aminoglycoside group but treatment is not usually attempted because the abscess is encapsulated, the organism is intracellular and response is poor. Subcutaneous abscesses can be treated with surgical drainage or extirpation.

CONTROL

Culling

A measure of control can be achieved by culling all animals with enlarged lymph nodes. Although this is a logical procedure it is worth noting that it is not capable of detecting early lesions, nor of detecting those animals with internal abscesses but no external abscesses. Ideally, control would be by the identification and culling of infected animals using serological testing. Culling on the basis of serological tests has been used but the sensitivity and specificity of current tests does not make this a perfect selection method.

Control of spread

All docking implements, ear taggers, and shears used for the Mules operation should be dipped in strong disinfectant before use. Similar attention should be given to the combs and cutters at shearing time. There should be good hygiene and disinfection in the shearing shed, especially of the shearing board and holding pens. Mobile shearing trailers should be cleaned and disinfected between farms. The importance of personal hygiene should be impressed on shearsers and farm-specific overclothing should be provided if possible. Younger age groups should be shorn first, rams second to last and any sheep with palpable lesions last. Pus spilled on the shearing floor should be cleaned up and the area disinfected. All shearing cuts should be disinfected. There can still be a high abscess rate in flocks that practice these control procedures.

Close contact of sheep following shearing should be avoided. All efforts must also be directed to avoid contaminating dipping fluid; one discharging abscess is capable of contaminating an entire tank of fluid. Dipping after shearing may be undesirable in badly affected flocks. The addition of an efficient bactericidal agent to the dipping fluid is worthy of consideration.

Goat housing should be free of wire or other causes of skin trauma, and communal use of equipment such as neck collars should be avoided. External parasites must be controlled. Goat herds that are free of the disease should avoid the purchase of animals from herds with a history of abscessation.

Vaccination

Vaccines formulated from concentrated, formalin-inactivated C. pseudotuberculosis culture supernatants containing phospholipase D have considerable efficacy and are available in many countries. Attenuated mutant vaccines also show promise. Vaccination does not provide complete protection against the development of abscesses but controlled field trials show a significant reduction in the number of sheep that develop abscesses and a reduction in the number of abscesses in infected sheep. Vaccinated sheep have fewer lung abscesses than unvaccinated sheep, in one study 96% fewer, and are less likely to spread infection from this source. Compliance with the recommended full course of the vaccine has an important influence on the efficacy of vaccination. An Australian study showed that flocks that followed the recommended protocol of two priming doses to lambs with yearly boosters to adult sheep throughout their life had an average slaughter prevalence of infection in sheep of 3%, whereas the average prevalence of lesional sheep at slaughter from flocks that only partially followed this protocol, by administering a single dose to lambs or not giving yearly boosters to adult sheep, varied from 22–33%.

Immunity to caseous lymphadenitis is believed to be associated with antitoxin activity and primarily cell-mediated, but colostral immunity will protect against experimental challenge at 6 weeks of life. Colostral immunity will also affect the development of immunity from
vaccination and lambs in flocks with a high prevalence of caseous lymphadenitis should not be vaccinated at less than 10 weeks of age.\(^4\)

Vaccination appears less successful in goats and, although it protects against experimental challenge and spread of the organism from the site of infection,\(^12,43\) there has been little protection from natural infection in field trials.\(^38,42\)

**PREVENTION**

All potential introductions to a flock should be examined clinically for evidence of disease. While this is not a particularly sensitive method of detection of infection, obvious clinical cases will be detected. Determining the infection status of the source flock is a safer procedure and purchase should be direct and not through markets. The ultimate method of prevention will include serological testing of individual animal introductions when adequate tests become available.

**ERADICATION**

Eradication is reported in endemically infected flocks by initial culling of all sheep with clinical signs and subsequent serological testing and culling of reactors. Seropositive ewes were allowed to lamb before culling but lambs were removed at birth, isolated from the infected dams and fed cow’s colostrum and milk replacer. These procedures were coupled with rigorous disinfection of facilities, removal of bedding and topsoil from barns and pens, isolation of seronegative sheep for 6 months from previously used pastures and tracks, and hygiene at skin-damaging management procedures. Serologically positive sheep were not detected after the second screening.\(^6\)

Total herd or flock eradication and replacement with infection-free animals is also possible.

**REVIEW LITERATURE**

**REFERENCES**

**BOLO DISEASE**

This disease of the fleece of sheep appears confined to the Eastern Cape province of South Africa and gets its name from the region where it was first described. An undclassified *Corynebacterium* sp. closely resembling *Corynebacterium pseudodiphtheriticum* and *Corynebacterium urealyticum* can be isolated from the skin of affected sheep.\(^1\) This organism is rarely isolated from the skin of sheep with normal fleeces.\(^2\) The disease can be experimentally reproduced by the topical application of the organism onto the intact skin of newly shorn sheep and sheep in 5 months wool, and the organism persists in the produced lesions for at least 169 days.\(^3\)

Bolo disease is a disease of medium- and medium–long–wool *Merino* sheep with dense fleeces containing a high yolk content. It occurs in sheep on natural grazing. There is no sex predilection but older sheep and poor-conditioned sheep are more severely affected. It can occur in semi-arid climates and there is no apparent seasonal or climatic influence or influence of external parasites.\(^4\) The attack rate in a flock can be as high as 90% and the disease has considerable economic impact, as the wool is of inferior quality and low economic value.

**Lesions** occur most commonly on the sides of neck and the shoulders, and are more easily seen in unshorn sheep as well.

**ETIOLOGY**

*Corynebacterium pseudotuberculosis* causes the classical disease. It is a soil-borne organism that gains access to tissue through wounds or insect bites. *C. pseudotuberculosis* possesses a cytotoxic surface lipid coat that appears to facilitate intracellular survival and abscess formation. It also produces a phospholipase exotoxin that increases vascular permeability, has an inhibitory effect on phagocytes and may facilitate spread of infection in the host. Biotypes associated with ulcerative lymphangitis in cattle

**Diagnosis** Culture of *C. pseudotuberculosis*

**Treatment** Drainage of abscesses and local treatment. Antibiotics of limited value

**Control** Housing hygiene. Herb security
and horses are different from the biotype associated with caseous lymphadenitis in sheep and goats.

**Epidemiology**

**Horses**

The disease was of considerable importance and widely distributed during the workhorse era but is now uncommon. The mortality rate was negligible but among the affected horses there was interference with their ability to perform. Infection occurs through abrasions on the lower limbs and is more likely when horses are crowded together in dirty, unhygienic quarters. Contact and inanimate transmission is the means of spread but passive transmission by flies is probable. As a rule only sporadic cases occur in a stable.

**Cattle**

**Occurrence**

Infection with *C. pseudotuberculosis* is uncommon in most countries but has importance in North Africa and Israel. It is one of the most commonly diagnosed infectious diseases in cattle in Israel.

The disease may present as ulcerative lymphangitis affecting the limbs, a cutaneous form with pyogranulomatous abscess formation in areas of the body, which may also be accompanied by mastitis or internal abscessation, or a necrotic and ulcerative dermatitis on the heel of the foot accompanied by edematous swelling and lameness. In a study recording the disease in 45 herds over a 13-year period the average morbidity rate was observed to be 6.4%. The disease occurred sporadically in 26 dairy herds, with morbidity rates of up to 5%, and in an epidemic form in 19 herds, in which the morbidity rate ranged from 5–35%. Outbreaks in herds have a course of approximately 5 months. Culling and mortality rates can approach 16%. The disease tends not to recur in a herd following an outbreak suggesting the development of herd immunity.

**Methods of transmission**

Infection may spread within the herd by direct contact between infected and uninfected animals, and by mechanical transmission by houseflies or other diptera. Spread between herds is by introduction of infected animals.

**Animal risk factors**

In Israel ulcerative lymphangitis and skin abscessation is more common in mature animals but necrotic and ulcerative dermatitis on the heel of the foot occurs in heifers.

**Environmental risk factors**

Both outbreaks and sporadic cases of the cutaneous form occur most commonly during the summer months (March to October) in Israel, which may be related to large populations of houseflies during these months. In contrast the peak incidence of necrotic and ulcerative dermatitis on the heel occurs during the winter months possibly due to conditions underfoot during this season. The organism can survive for prolonged periods in contaminated environments under favorable conditions.

**Economic importance**

In cattle, the economic losses are associated with high culling rates, a decrease in average monthly milk production and an increase in the bulk tank milk somatic cell count.

**Zoonotic implications**

The infection can be zoonotic and human infection can occur as a result of continued close contact with infected animals. Consumption of infected unpasteurized milk can also be a risk for human infection.

**Pathogenesis**

Infection of skin wounds is followed by formation of lymphatic vessels and the development of abscesses along their course. Generalized lymph node involvement is unusual. The organism possesses a cytotoxins surface lipid coat that appears to facilitate intracellular survival and abscess formation and produces a phospholipase exotoxin that increases vascular permeability and has an inhibitory effect on phagocytes.

**Clinical Findings**

**Horses**

Ulcerative lymphangitis. In horses the initial wound infection is followed by swelling and pain of the pastern, often sufficient to cause severe lameness. Nodules develop in the subcutaneous tissue, particularly around the fetlock. This is followed by infection of lymphatic vessels and the development of abscesses along their course. Spread to other subcutaneous sites on all parts of the body can occur. These may enlarge to 5–7 cm in diameter and rupture to discharge a creamy green pus. The resulting ulcer has ragged edges and a necrotic base. Lymphangitis draining the area become enlarged and hard and secondary ulcers may develop along them. Lesions heal in 1–2 weeks but fresh crops may occur and cause persistence of the disease for up to 12 months.

**Cattle**

Ulcerative lymphangitis. The lesions in cattle are similar to those in horses except that there may be draining lymph node enlargement and the ulcers discharge a gelatinous clear exudate.

**Cutaneous form.** Single or multiple painful abscesses occur in the skin and subcutaneous tissue on the head, flanks, shoulders, neck, and hind legs above the stifle joint. Abscesses can reach a diameter of 15–20 cm and have a firm, fibrous tissue capsule. Abscesses ulcerate and develop draining tracts. Ruptured abscesses discharge serosanguinous exudates or blood-stained yellowish pus. The regional draining lymph nodes are enlarged but generalized lymphangitis does not occur. Recurrence occurs in a small percentage of animals following initial recovery.

**Necrotic and ulcerative dermatitis on the heel of the foot.** Lameness is apparent and there is edematous swelling on the distal part of the legs associated with a necrotic-ulcerative dermatitis on the heel of the foot.

**Clinical Pathology**

The isolation of *C. pseudotuberculosis* from discharging lesions is necessary to confirm the diagnosis. There are no serological tests validated for infection in cattle or horses but serological tests used for serological diagnosis of caseous lymphadenitis in sheep are used for diagnosis of *C. pseudotuberculosis* in horses in some laboratories.

**Differential Diagnosis**

**Horses**

- Epizootic lymphangitis
- Glanders
- Sporotrichosis
- Rhodococcus equi

**Cattle**

- Digital dermatitis
- Dermatophilus congolensis

**Treatment**

*C. pseudotuberculosis* is sensitive to all common antimicrobial drugs with the exception of the aminoglycoside group, but systemic treatment of infected animals does not affect the recovery period. Local treatment of ulcers is the usual and most effective procedure but parenteral injections of penicillin or tetracycline may be necessary in severe cases. In the early stages an autogenous bacterin may have value as treatment.

**Control**

Good hygiene in stables and under-foot, careful disinfection of injuries to the lower limbs usually afford adequate protection against ulcerative lymphangitis. With all...
manifestations, isolation of the affected animals and local treatment with antibiotics to prevent the disease from spreading to other animals in the herd. Infected animals should not be introduced to a naive herd and there should be adequate fly control.

CONTAGIOUS ACNE OF HORSES
(CANADIAN HORSE POX, CONTAGIOUS PUSTULAR DERMATITIS)

Contagious acne of horses is characterized by the development of pustules, particularly where the skin comes in contact with harness.

ETIOLOGY
Corynebacterium pseudotuberculosis is the specific cause of this disease.

EPIDEMIOLOGY
The disease is spread from animal to animal by means of contaminated grooming utensils or harness. An existing seborrhea or folliculitis due to blockage of sebaceous gland ducts by pressure from harness probably predisposes to infection. Inefficient grooming may also be contributing cause.

Contagious acne is of limited occurrence and causes temporary inconvenience when affected horses are unable to work.

PATHOGENESIS
Infection of the hair follicle leads to local suppuration and the formation of pustules which rupture and contaminate surrounding skin areas. Occasional lesions penetrate deeply and develop into indolent ulcers.

CLINICAL FINDINGS
The skin lesions usually develop in groups in areas which come in contact with harness. The lesions take the form of papules which develop into pustules varying in diameter from 1-2.5 cm. There is no pruritus but the lesions may be painful to touch. Rupture of the pustules leads to crust formation over an accumulation of greenish-tined pus. Healing of lesions occurs in about 1 week but the disease may persist for 4 or more weeks if successive crops of lesions develop.

CLINICAL PATHOLOGY
Swabs of the lesions can be taken to determine the presence of C. pseudotuberculosis.

DIFFERENTIAL DIAGNOSIS
- Ringworm
- Staphylococcal pyoderma
- Nodular necrobiosis

Diagnostic confirmation
Isolation of C. pseudotuberculosis from lesions.

TREATMENT
Affected animals should be rested for several days. Frequent washing with a mild skin disinfectant solution followed by the application of antibacterialointments to the lesions should facilitate healing and prevent the development of further lesions. Parenteral administration of antibiotics may be advisable in severe cases.

CONTROL
Infected horses should be rigidly isolated and all grooming equipment, harness and blankets must be disinfected. Grooming tools must be disinfected before each use. Vaccination is not likely to be effective because of the poor antigenicity of the organism.

RHODOCOCCUS EQUI
PNEUMONIA OF FOALS

ETIOLOGY
Virulent strains of Rhodococcus equi, based on pulsed-field gel electrophoresis of chromosomal DNA.

EPIDEMIOLOGY
Sporadic disease of 1-5-month-old foals that is endemic on some farms. Foals are infected by ingestion or inhalation during first weeks of life.

Clinical signs
Pneumonia, fever, respiratory distress, cough, lack of nasal discharge, failure to thrive, multiple distended joints and uveitis. Occasionally diarrhoea or septic osteomyelitis.

Clinical pathology
Leukocytosis, hyperbrinogenemia, inflammatory cells in tracheal aspirate.

Necropsy lesions
Pulmonary consolidation and abscession. Nonseptic polyarthritis.

Diagnostic confirmation
Culture of R. equi from tracheal aspirate.

Treatment
Erythromycin estolate or clindamycin. Clindamycin (7.5 mg/kg every 12 hours) or amoxicillin (25 mg/kg every 12 hours) in combination with rifampin 5 mg/kg every 12 hours orally.

Control
Insure adequate transfer of passive immunity. Decrease stocking density. Decrease environmental contamination by virulent strains of R. equi.

ETIOLOGY
Rhodococcus equi is a Gram-positive, pleomorphic rod. The most important manifestation of R. equi infection is pneumonia in foals. It also causes pleuropneumonia, pneumonia, osteomyelitis, and abortion in immunocompromised and normal adult horses, abscesses that must be differentiated from tuberculosis in pigs and ruminants, and pneumonia in immunosuppressed animals.5 The organism is a natural inhabitant of soil, grows well at temperatures ranging from 10-40°C, and is readily isolated from the feces of herbivores and their environment. However, isolates of R. equi vary in virulence, with many isolates obtained from feces or soil not being pathogenic.6

There are a large number of virulent strains of R. equi, based on pulsed-field gel electrophoresis of chromosomal DNA.7 There is evidence of clustering of strains on farms and on most farms 1 or 2 strains predominate, there is little evidence of marked regional variations in prevalence of strains of virulent R. equi.7 Only rarely will it be possible to link infections to a given site or region on the basis of analysis of chromosomal DNA.

Virulence of R. equi is dependent upon the ability of the organism to enter, survive in and replicate in macrophages. Virulence is associated with the presence of highly immunogenic virulence associated proteins (Vap A, C, D, E, G, H), of which Vap A is apparently the most important, although the role of the other Vap proteins has not been determined.9 Vap A is a membrane protein, a lipid-modified protein that elicits an immune humoral response by foals.10 Expression of Vap A, C, D, and E is upregulated by incubation at 37°C, consistent with their role as virulence factors. Other genes probably involved in virulence are also upregulated by conditions that mimic those in vivo.11 The presence of the virulence proteins is associated with enhanced ability of virulent R. equi to survive and replicate within macrophages, whereas avirulent strains replicate poorly or not at all.12 However, the exact virulence mechanisms of R. equi are not known.13

The genes for Vap A and C-H are present in a pathogenicity island in an 80-85 kb plasmid that is present in 98% of isolates of R. equi from foals with pneumonia.14 Most isolates from the environment, feces, pigs, cattle, and human patients with R. equi infection do not contain either of the two identified virulence plasmids.15,16 Virulence is associated with the presence of the plasmid, and loss of the plasmid by a strain of R. equi results in loss of virulence. There is geographical variation both within and between countries in the prevalence of each of the virulence plasmids in isolates from foals with pneumonia.15,17,18

EPIDEMIOLOGY
Occurrence
R. equi pneumonia in foals has a worldwide distribution. Clinical disease is often
sporadic but on farms where the disease is endemic, annual morbidity can be as high and can vary widely from year to year. The median percentage of foals that developed *R. equi* at farms on which the disease was endemic was 6.6%, with 38% of farms having more than 10% of foals affected. Case fatality rates for foals on farms, as opposed to those treated at veterinary teaching hospitals, is reported to be 29–42% (for 113 and 19 affected foals, respectively). The median case fatality rate for 32 farms in Texas was 25% and the case fatality rate was more than 50% for 22% of farms. The case fatality rate among foals treated at veterinary teaching hospitals is approximately 28%. The detection of *R. equi* pneumonia in one foal on a farm should prompt an examination of all other foals on the farm. Current evidence supports the hypothesis that foals are exposed and infected within the first several days of life. The age at onset of clinical signs of disease associated with *R. equi* varies between 2 weeks and 6 months but the peak prevalence for pneumonia disease is between 1 and 3 months. The disease is rare in adult horses. Risk factors in foals for development of *R. equi* pneumonia have not been determined although a large number of factors have been examined. The month in which the foal was born, gestational age, dam's parity, antimicrobial administration during the first week of life, exposure to pasture at less than 2 weeks of age, need for treatment to correct inadequate transfer of passive immunity, and size of mare/foal groups were not associated with risk of disease on farms in Texas. The prevalence of virulent *R. equi* in isolates from the environment does not appear to be greater on farms where the disease is endemic. Morbidity varies widely among geographical areas and individual farms, probably because of environmental factors that affect the number of virulent *R. equi* and the ease of infection. Because aerosol infection by virulent *R. equi* in dust is thought to be the most important route of infection, factors that favor the accumulation and persistence of *R. equi* in soil and its ability to become aerosolized most probably increase the risk of infection. Such factors might include:

- Hot and dry weather, favoring formation of dust
- Soil pH, salinity and concentrations of various elements including iron, zinc, and copper are not associated with the risk of foals developing *R. equi* pneumonia on farms in Texas. These soil-associated risk factors were examined because *R. equi* is a normal inhabitant of the soil and of the intestine of ruminants, horses, and pigs. It is not highly resistant but it has been found to survive in moist soil for periods of longer than 12 months. The infection is considered to be soil associated and to be maintained through a soil–horse cycle. The number of organisms in the soil and stable areas on horse farms increases with the time that the farms have housed horses, although there is not a strong correlation between *R. equi* concentration in soil and prevalence of pneumonia in foals.

**Diseases associated with Corynebacterium, Actinobaculum, and Arcanobacterium species**

**PATHOGENESIS**

Exposure of foals to *R. equi* is common, based on rate of seroconversion, yet the development of respiratory infection and clinical disease is much less common. The reason for this is not fully understood, although development of the disease probably depends on exposure to an infectious dose of organism and the susceptibility of the foal. Recent epidemiology studies suggest that exposure occurs within the first few days of life, before waning of maternally derived passive immunity, and that affected foals have lower CD4+:CD8+ ratios before development of the clinically apparent disease than foals that do not subsequently develop the disease. The differences between groups of foals was largest during the first 2 weeks of life, suggesting that foals that subsequently develop disease associated with *R. equi* may have impaired immune function during early life. In adult horses, in which the disease is rare, protective immunity is associated with both cellular and humoral immune responses characterized by enhanced immunoproliferative responses of CD4+ and CD8+ cells and presence of IgGa and IgGb antibodies to *R. equi*. Opsonizing antibody to *R. equi* is an important defense mechanism in experimentally infected foals and administration of *R. equi* hyperimmune plasma or plasma rich in anti-Vap A and C antibodies protects experimentally infected foals from developing pneumonia. Overall, these results suggest that foals that develop *R. equi* pneumonia have a Th1 helper cell (Th1) response to infection, rather than a Th2-like response. Whether the switch to a Th2-like response to infection is a function of virulent *R. equi* or an attribute of susceptible foals has not been determined.

Experimental and clinical studies indicate that the foal is infected several weeks or months before clinical signs are observed. Virulent strains of *R. equi* are facultative intracellular parasites of macrophages, which they ultimately destroy. Neutrophils are bactericidal for *R. equi* but the organism can survive by inclusion in macrophages. Opsonization of *R. equi* by specific antibodies results in enhanced lysosome–phagosome fusion and greater killing of *R. equi* by equine macrophages and monocytes, whereas entry of *R. equi* into macrophages by nonimmune phagocytosis is not associated with enhanced killing. Its survival in the macrophage is associated with absence of phagosome–lysosome fusion. Nonvirulent strains do not proliferate in macrophages and monocytes. The combined action of humoral
and cellular immune systems is important in preventing development of the disease after inhalation of bacteria. Without opsonization, the capacity of the pulmonary macrophage of foals to kill *R. equi* is impaired and the organism has been shown to be able to persist in the pulmonary macrophage of infected foals. The inability of the pulmonary macrophages to destroy *R. equi* leads to persistent infection in the lung and a chronic bronchopneumonia with extensive abscessation and an associated suppurative lymphadenitis.

Intestinal infection is common in foals with *R. equi* pneumonia, although clinical manifestations of the intestinal infection, such as diarrhea, are uncommon. Gastrointestinal tract infection is characterized by ulcerative lesions of the mucosa of the large intestine and cecum. In rare cases bacteremia and subsequent suppurative foci may develop in many organs, including bones and joints, liver, kidneys, and subcutis.

**CLINICAL FINDINGS**

*R. equi* pneumonia of foals may present as an acute onset of inappetence, fever, depression and tachypnea or as a more chronic disease characterized by cough and failure to thrive. The former presentation is more common and usually occurs in foals less than 3-4 months of age, with younger foals being more severely affected. It is important to realize that the acute onset of the disease is preceded by a long incubation period during which clinical signs are minimal and that the development of clinical signs is associated with severe and extensive lung lesions. The foal is often in respiratory distress and is reluctant to move and to suckle. Cyanosis may be present in severe cases. Auscultation of the chest may reveal crackles and wheezes, but abnormal lung sounds are often much less apparent than the severity of the respiratory disease suggests they should be. Foals with *R. equi* abscesses may not have abnormal lung sounds. There is usually minimal nasal discharge.

Subcutaneous abscesses, osteomyelitis and septic arthritis may be present or develop. Many foals (20%) have an aseptic polyarthritis, evident as nonpainful dis­ tension of joints, at the time they develop signs of respiratory disease. Immunemediated uveitis occurs in approximately 10% of severely affected foals.

In older foals the disease assumes a characteristic clinical syndrome marked by development of severe lesions without clinical signs in the foal. A subacute pneumonia develops slowly with coughing, an increase in the depth of respiration with respiratory distress developing in the late stages, and characteristic loud, moist crackles or ‘rattles’ on auscultation. The foal continues to suck and the temperature is sometimes normal but the foal becomes emaciated. Severe diarrhea may follow on accompany the respiratory signs. Nasal discharge and lymph node enlargement in the throat regions are absent. Severely affected animals die in 1–2 weeks. Thoracic auscultation may not reveal any abnormalities during the preclinical stage of the disease, although careful auscultation when tidal volume of the foal is increased by exertion or use of a rebreathing bag can reveal localized wheezes and crackles or changes in the intensity of normal breath sounds (indicative of areas of lung consolidation).

Radiographic examination is a valuable aid in diagnosis and in monitoring progress in hospitalized foals. Affected animals show evidence of consolidation of lung tissue, lymphadenopathy, and cavitating lesions in the lungs. Ultrasonographic examination of the chest may reveal the presence of pulmonary consolidation before clinical signs are apparent and is useful means of detecting subclinical disease.

When lesions are confined to the intestinal wall the predominant clinical sign will be diarrhea, which may be acute or chronic and intermittent. Intra-abdominal abscesses are associated with ill-thrift, weight loss, variable abdominal distension, fever, depression and in some cases colic. Ultrasonographic examination can reveal the abscesses provided that it is within the field of the ultrasound probe.

**PROGNOSIS**

*R. equi* infection in Thoroughbred and Standardbred foals is associated with a reduced chance of racing as an adult compared with the overall population of foals, but affected foals that survive have a similar racing performance as adults to horses that did not have *R. equi* pneumonia. The morbidity and case fatality rates are provide above under Epidemiology.

**CLINICAL PATHOLOGY**

Hematological evaluation usually reveals leukocytosis with neutrophilia and monocytosis, and elevation in the concentrations of acute phase proteins including plasma fibrinogen and serum amyloid A – changes characteristic, but not diagnostic, of *R. equi* infection. Monitoring of blood white cell concentration and plasma fibrinogen concentration are useful in foals from farms on which the disease is endemic. White blood cell concentrations above 13.0 × 10^9/L (13 000 cells/μL) have a sensitivity and specificity of 95% and 61% respectively for *R. equi* pneumonia. The high sensitivity means that few foals with the disease will be missed, while the moderate specificity means that a number of foals will be incorrectly suspected as having the disease. Because a high white cell count can be caused by a number of diseases other than *R. equi* pneumonia, foals with high white cell counts from farms on which the disease is endemic should be further examined for evidence of disease, including detailed clinical examination possibly including ultrasonographic examination, culture or PCR of tracheal aspirates, or thoracic radiography. Measurement of plasma fibrinogen concentration is less useful for detecting foals with *R. equi* pneumonia. Plasma fibrinogen concentrations of 400 mg/dL (0.4 g/L) have sensitivity and specificity of 91% and 51%, respectively, whereas concentrations of 600 mg/dL (0.6 g/L) have sensitivity and specificity of 38% and 96%, respectively. The positive and negative predictive values of the tests depends on the prevalence of the disease among the group of foals examined, being lower for farms on which the disease is rare and increasing as the prevalence of the disease increases. Serial measurement of *serum amyloid A* concentrations is not useful for detecting foals with clinically inapparent *R. equi* pneumonia, nor do foals with pneumonia reliably have higher serum amyloid A concentrations than normal foals.

Transthreacal aspirates from affected foals reveal a neutrophilic leukocytosis. Intracellular, Gram-positive pleomorphic rods characteristic of *R. equi* may be present in tracheal aspirates but the sensitivity of this observation has not been determined and all transtracheal aspirates should be cultured.

Although numerous serological tests have been developed, including agar gel immunodiffusion, synergistic hemolysis inhibition, radial immunodiffusion and various ELISAs, none has demonstrated value in the diagnosis of the disease in individual animals. Currently available serological tests, either as single or paired samples, are not reliable in confirming or excluding the presence of *R. equi* pneumonia in foals.

Culture of tracheal aspirates is the gold standard for antemortem diagnosis of the disease, although sensitivity of culture is less than that of PCR examination of tracheal aspirates. Culture of tracheal aspirates has a sensitivity of approximately 86%, based on diagnosis of *R. equi* pneumonia at necropsy. However, *R. equi* can be cultured from 35% of clinical normal foals in populations in which the disease is endemic. A PCR test for the rapid detection of *R. equi* in tracheal aspirates has a sensitivity of 100% and a specificity of 91% in foals with a clinical diagnosis of *R. equi* pneumonia. PCR examination of nasal swabs for presence of *R. equi* has a
sensitivity of 15%, which is too low to be clinically useful. More recent quantitative real-time PCR assays permit the rapid detection and quantification of virulent (VapA-gene-positive) strains of R. equi in tracheobronchial aspirates. This assay detects R. equi at concentrations as low as 20 cfu/mL of tracheobronchial fluid, providing a specific and highly sensitive test for the presence of this organism. A multiplex PCR test simultaneously detects R. equi and the presence of virulence factors, thereby permitting rapid differentiation of pathogenic from nonpathogenic strains of R. equi in biological samples.

**Necropsy Findings**

The predominant lesions are a pyogranulomatous pneumonia plus lymphadenitis of the bronchial lymph nodes. Grossly, the firm, raised lung nodules may reach several centimeters in diameter and be located anywhere in the lung field, especially in the cranioventral quadrant. If several nodules coalesce, the lesion may be misinterpreted as a suppurative bronchopneumonia. Histologically, organisms are easily demonstrated within the macrophages and giant cells comprising these lesions. Many cases also have ulcerative enterocolitis, with abscessation of mesenteric and cecal lymph nodes. Although necropsy may reveal widespread infection, many cases are subclinical.

**Samples for postmortem diagnosis**

- Bacteriology – chilled lung, affected lymph nodes and swabs from atypical sites (CULT)
- Histology – formalin-fixed lung, lymph node, and colonic lesions.

**Diagnostic Confirmation**

Antemortem diagnosis is by culture of R. equi from aspirates of tracheal fluid. Currently available serological tests do not provide confirmation of disease in individual animals.

**DIFFERENTIAL DIAGNOSIS**

The pneumatic form of the disease may be confused with other causes of pneumonia in foals (Table 16.4). Other causes of diarrhea in this age group include parasitism due to cyathostomes, infection by Salmonella sp. and antibiotic-induced diarrhea.

- The aseptic synovitis and joint effusion that frequently accompanies R. equi pneumonia should be differentiated from septic arthritis due to S. zooepidemicus, Salmonella spp., R. equi or other bacteria.

**TREATMENT**

The principles of treatment are cure of R. equi infection, relief of respiratory distress and correction of associated immunemediated diseases.

Elimination of infection requires the administration of antimicrobial agents that are both effective against the organism and able to penetrate infected macrophages to gain access to the organism. In
vitro antibiotic sensitivity testing has not been demonstrated to be useful in predicting the clinical efficacy of treatment. R. equi isolates from ill foals are frequently sensitive in vitro to a variety of antibiotics, including the aminoglycosides gentamicin and neomycin, tetracycline, sulfonamides and chloramphenicol, while most are resistant to cephalosporins and penicillin.53,55 However, treatment with antibiotics other than erythromycin and rifampin is associated with a lower recovery rate. Treatment with penicillin, with or without gentamicin, chloramphenicol or tetracycline, is not effective.53

Trimethoprim-sulfadiazine combinations might be effective in some foals but are not the preferred treatment.53 Neomycin has been recommended for treatment of R. equi pneumonia, but the risk of nephrotoxicosis, need for parenteral administration and lack of demonstration of clinical efficacy do not support its use at this time.

The treatment of R. equi pneumonia in foals is achieved by administration of macrolide antibiotics in combination with rifampin. Conventional treatment is the administration of the combination of an acid-stable erythromycin (preferably estolate) at a dose of 25 mg/kg orally every 12 hours and rifampin at a dose of either 5 mg/kg every 12 hours or 10 mg/kg every 24 hours. Other esters or preparations of erythromycin are less well absorbed or have shorter elimination half-lives than the estolate ester and must be administered more frequently.32 Erythromycin ethylsuccinate does not provide optimal therapy for R. equi pneumonia in foals because of poor absorption after oral administration.55,57

The macrolide antibiotics azithromycin and clarithromycin have also been used to treat foals with R. equi pneumonia. Treatment of foals with a combination of clarithromycin (7.5 mg/kg orally every 12 h) and rifampin results in improved survival over foals treated with azithromycin (10 mg/kg orally every 24 h) and rifampin or erythromycin and rifampin in a veterinary teaching hospital.58

Therapy should be continued until the foal is clinically normal and has a normal plasma fibrinogen concentration and white blood cell count, which can require treatment for at least 1 month and often longer. Radiographic or ultrasonographic demonstration of resolution of the pulmonary consolidation and abscessation is useful in the decision to stop therapy. The case fatality rate is approximately 30% (see Epidemiology, above) even with appropriate treatment

Side-effects of erythromycin—rifampin therapy include the development of diarrhea in some foals and their dams.59

Administration of erythromycin to foals is associated with an eightfold increase in the risk of diarrhea.50 Antibiotic therapy should be temporarily discontinued in foals that develop diarrhea.

During hot weather, some foals treated with erythromycin become hyperthermic (40–41°C, 104–105.5°F) and tachypneic and occasional deaths result from this syndrome.50,60 The basis for this hyperthermic event, which may occur in healthy foals administered erythromycin, is unknown. Affected foals should be treated urgently with antipyretics, cold water bathing and housing in a cooler environment.

The emergence of R. equi isolates resistant to rifampin during therapy of foals with R. equi pneumonia has been reported.61 However, one case had an atypical clinical course, in that the foal was 10 months of age at presentation and may have been immunosuppressed, and in the other instance the foal was treated with only rifampin. The development of resistance during monotherapy with rifampin is a recognized contraindication to the use of this drug alone.

Ancillary therapy with NSAIDs, bronchodilators, and mucolytics might be of value.53 Foals in severe respiratory distress require intranasal or intratracheal administration of oxygen.

CONTROL

Control measures are designed to maximize the resistance of the foal to infection and to reduce the infection pressure on the foal by decreasing contamination of the foal's environment with virulent R. equi.

Insuring adequate transfer of colostral immunoglobulins in all foals through routine monitoring of serum immunoglobulin concentrations in 1-day-old foals is an essential part of any control program.

To decrease environmental contamination with virulent R. equi, efforts should be made to reduce fecal contamination of pastures and to reduce or eliminate dusty or sandy areas.34,62 These efforts should include grassing or paving bare areas, removal and composting of faecal material on a regular basis, reduction of stocking density and reduction in the size of mare/foal bands.24

On farms with endemic disease, regular physical examination, including auscultation of foals and once-daily monitoring of rectal temperature, can permit early identification and treatment of affected foals.53 Measurement of blood white cell count, as detailed above, can be useful in early identification of affected foals. Identification of one foal affected with R. equi pneumonia on a farm should prompt an examination of all other foals on the farm.

Ultrasonographic examination of the thorax of foals may permit identification of foals with clinically inapparent pulmonary abscesses.

The administration to foals of a hyper-immune serum, obtained from mares vaccinated with an autogenous vaccine, limits the severity of disease produced by experimental challenge but has not been consistently useful in preventing or decreasing the prevalence of naturally occurring disease.19,34,46 There are no vaccines effective in prevention of R. equi pneumonia in foals.

Diseases associated with *Listeria species*

There are currently six species classified within the genus *Listeria* but only *Listeria monocytogenes* and *Listeria innocua* (previously classified as *L. monocytogenes* serotype S) are pathogenic for domestic animals. *L. innocua* is only mildly pathogenic and is an occasional cause of abortion in sheep and cattle. Aborted fetuses have suppurrative broncho-pneumonia and lack the multifocal hepatocellular necrosis commonly seen in abortions associated with *L. monocytogenes*. *Listeria innocua* is occasionally associated with encephalitis in ruminants that is clinically and pathologically similar to that associated with *L. monocytogenes*. Most, but not all, reports of both infections record that the animals were being fed silage.

**REFERENCES**

- Gastroenteritis has been reported primarily by veterinary diagnostic labs in Great Britain and New Zealand as a sporadic disease affecting all ages of sheep after weaning. It occurs during the winter months most commonly in sheep fed baleage or silage. Cases occur 2 days or more after the onset of feeding. Less commonly, cases occur in sheep on root crops or on pasture where the quality of the pasture is poor and they are at high stocking densities.

- Mastitis is uncommon but can occur in cattle, sheep, and goats. It results in contamination of milk with *L. monocytogenes*. The more common source of *L. monocytogenes* in raw milk is fecal contamination. In a Danish study of quarter milk samples from over 1,000,000 cows in 36,199 herds, 0.4% of cows had listerial mastitis and 1.2% of herds had infected cows.

### Source of infection

The organism is common in the environment and infection is not limited to agricultural animals. *L. monocytogenes* has been isolated from 42 species of mammals, 22 species of birds as well as fish, crustaceans, and insects. It is truly ubiquitous in the environment and can be commonly isolated from animal feces, human feces, farm slurry, sewage sludge, soil, farm water troughs, surface water, plants, animal feeds and the walls, floors, drains, etc. of farms and other environments.

The ability to form biofilms may assist in its survival in the environment and may assist in perpetuating its presence in water troughs on infected farms.

Most feed hays, grains and formulated feeds have the potential to contain *L. monocytogenes* but, with most, low levels of available water restrict its multiplication.

In ruminants *L. monocytogenes* can be isolated from the feces and nasal secretions of healthy animals and has been isolated from the feces of cattle in 46% of 249 herds examined and from 82% of samples of feedstuffs. In temperate climates the prevalence of *L. monocytogenes* in the feces of ruminants appears to vary with the season, being higher in the winter period. It is also increased during periods of environmental stress and in association with the stress of lambing and transport. The presence in feces and secretions can also be influenced by the numbers of the organism in feeds fed to the animals. In herds where there is a high proportion of cattle excreting in the feces, the organism can be isolated from dried fecal dust on walls and most farm surfaces.

*L. monocytogenes* is not isolated from the feces or environment in all farms and its presence in isolable numbers is largely a reflection of its presence in feed, or the presence of animals with intestinal carriage. It is apparent that in some healthy herds and flocks there may be a multitude of different strains in the silage and feed, water troughs, feces and environment in a single herd.

The presence of *L. monocytogenes* in bulk tank milk or milk filters is used as a measure of farm infection prevalence. Obviously this measure is influenced by the management and environmental conditions on farms that might result in fecal contamination of the teats. Although bulk tank and milk filter infection rates provide information of possible value to measures of environmental contamination and risk for human exposure there is no evidence that this measure has any relation to risk for animal disease on the farm being studied.

Silage

*L. monocytogenes* is commonly present in silage, but it does not multiply to any significant extent in effectively preserved silage which is characterized by anaerobic storage, high density, a high concentration of organic acids, and a pH below 4.5. *Listeria* can multiply in silage above pH 5.0–5.5, the critical pH depending upon the dry matter content. *L. monocytogenes* may be present in silage which is poorly fermented but can also occur in pockets of aerobic deterioration in otherwise good silage and this is the common occurrence. These areas are often indicated by mold growth and occur at the edges of the clamp and in the top few inches of the surface in plastic-covered clamps where air has circulated under the plastic. Thus the growth of *L. monocytogenes* is a surface problem in silage – except those that are poorly fermented – and occurs in small areas sporadically over the surface of a silage. The risk for contamination of silage with *Listeria* is higher when it contains soil.

Soil may be incorporated from mole-hills present in the field and it may also be incorporated in the front of the clamp during final packing. An ash content of greater than 70 mg/kg dry matter indicates soil contamination.

**Big bale silage** may have a higher risk for listerial infection than conventional silage because of its lower density. Poorer fermentation, the greater surface area relative to clamp silage and the greater risk for mechanical damage to the plastic covering.

**Moist preserved feeds** other than grass silage are at risk for listerial growth; listeriosis is recorded, for example, in association with the feeding of moist brewers' grains, wet spoiled hay bales and silage made from commodity by-products such as orange and artichoke waste. A relatively rapid method for the quantitative assessment of the occurrence and distribution of *Listeria* in suspect silage is available.

Infective material also derives from infected animals in the feces, urine, aborted fetuses and uterine discharge, and in the milk. Although immediate spread among animals in a group has been demonstrated, field observations suggest that medi­ate contagion by means of inanimate objects also occurs. **Woody browse** may be a risk factor for goats.

### Transmission

With septicemic disease and abortion the organism is transmitted by ingestion of contaminated material. Lambs which develop septicemic disease may acquire infection from contamination on the ewe's teat, from the ingestion of milk containing the organism from ewes or does with subclinical bacteremia, through the navel from the environment, and also as a congenital infection. The encephalitic form of the disease results from infection of the terminals of the trigeminal nerve consequent to abrasions of the buccal mucosa from feed or browse or from infection of tooth cavities. Spinal myelitis is believed to result from growth up spinal nerves subsequent to body area infections.

Outbreaks of encephalitis which occur in sheep after introduction to silage usually commence about 3–4 weeks later, although there is wide variation and one study of a large number of outbreaks found the median time of this period to be 44 days. This delay reflects the time for ascending infection.

Commonly, the serotype that is isolated from the brain of an affected animal is also present in the silage being fed. However, the recent development of methods for genetic analyses of *L. monocytogenes* has demonstrated that serotyping is a relatively crude tool for epidemiological studies and in many instances, although the isolate from brain may be the same serotype as that from silage, there is no relationship on genetic analysis. Possibly this reflects differences in strains at different sites in silage and the difference between the time of sampling of the silage and the time when the affected cow ate it.

Septicemic disease in sheep and goats usually occurs within 2 days of introduction to silage and abortions 6–13 days later.

### Risk factors

Despite the ubiquity of *L. monocytogenes*, only a small proportion of animals develop clinical disease. A number of predisposing factors have been observed, or proposed, as risk factors for disease. These include factors that cause a lowering of the host animal's resistance and factors that increase...
the infection pressure of the organism. In farm animals the latter appear the most important.

Host management risk factors

Observed risk factors include:

- Poor nutritional state
- Sudden changes of weather to very cold and wet
- The stress of late pregnancy and parturition
- Transport
- Long periods of flooding with resulting poor access to pasture.

Area outbreaks affecting several flocks can occur in sheep on poorly drained and muddy pastures following floods, but outbreaks are also described in droughts. Overcrowding and insanitary conditions with poor access to feed supplies may predispose housed sheep.

Breed difference in susceptibility (Angora goats and Rambouillet sheep) has been observed in some studies but not in others.

Pathogen risk factors

Factors that increase the infection pressure largely involve a massive multiplication of L. monocytogenes in the feed or environment. The feeding of grass or corn silage as a major risk factor for the occurrence of listeriosis has been recognized for many decades. The increase in use of silage for feed in ruminants may be the reason for the apparent increase in the prevalence of the disease in recent years. Silage may also exert its effect by increasing the susceptibility of the host to listerial infection, although this has been disputed.

Introduction of virulent strains to the flock may also occur via a carrier animal, and birds, such as seagulls that scavenge on sewerage areas, may carry a heavy population of the bacteria and can contaminate feed or pastures for silage. The organism persists for as long as 3 months in sheep feces and has been shown to survive for up to 11.5 months in damp soil, up to 16.5 months in cattle feces, up to 207 days on dry straw and for more than 2 years in dry soil and feces. It is resistant to temperatures of -20°C (-6°F) for 2 years and is still viable after repeated freezing and thawing.

Experimental reproduction

Oral or parenteral challenge of nonpregnant sheep and goats will produce a bacteremia. Lactating animals secrete the organism in milk during the bacteremic period. Prior challenge of goats with L. monocyto-genes does not protect against subsequent challenge with L. monocytogenes.

Several studies have shown that oral, conjunctival, and parenteral challenge of pregnant animals results in more severe signs of septicemia and can be followed by abortion, although this is not an invariable sequel. Encephalitis has not been reproduced experimentally by intravenous challenge, although meningoencephalitis may occur following this route of challenge in young lambs. Encephalitis has been reproduced experimentally by the injection of organisms into the buccal mucosa or the tooth pulp cavity, the organism traveling centripetally via the trigeminal nerve to reach the brain stem.

Zoonotic implications

In humans, listeriosis may occur as a sporadic disease or as a food-borne outbreak to produce septicemic disease, meningoencephalitis, abortion and infection in other organs. Sporadic disease may involve healthy humans of any age but the disease usually occurs in the very young or unborn, the very old and people who are otherwise immunocompromised. The case fatality is high, and overall approximately 25% of reported cases die. Active surveillance for sporadic cases indicates that approximately 2000 cases and 450 deaths occur each year in the USA to give an annual incidence of 0.8 per 100,000 population. The incidence is increasing, possibly because of an increase in susceptible populations.

The similarity of the disease spectrum in humans and animals and the occurrence of food-borne outbreaks has led to concerns that the disease could be a zoonosis. Whereas there is a potential for zoonotic transmission it would appear that the majority of human exposures to the organism, and the risk for disease, result from contamination of foods during processing and from the particular ability of the organism to grow at refrigeration temperature.

Milk products

Milk products have been incriminated in some outbreaks of disease. Numerous studies have shown that L. monocytogenes is commonly present in low numbers (usually less than 1/mL) in raw milk from some herds. In the vast majority of herds this is the result of fecal contamination during the milking process or other environmental contamination. Rarely, its presence in raw milk is from an animal with subclinical mastitis and in this case its numbers in bulk tank milk are much higher (2000-5000/mL), even when there is a single cow or goat with L. monocytogenes mastitis.

In goats and sheep the presence in raw milk may also be the result of a subclinical bacteremia.

There have been concerns that the organism might survive pasteurization, especially if present in phagocytes. D-values for Listeria in milk have been determined to be in the range of 0.9 seconds at 71.1°C. The legal limit for high-temperature/short-time pasteurization in the US is 71.7°C for 15 seconds and this temperature is sufficient to inactivate numbers far beyond those present in raw milk. There is no evidence that the organism will survive correct pasteurization procedures.

Bulk tank infection rates are higher in winter and spring and cross-sectional and case-control studies have shown that the risk for detecting L. monocytogenes in bulk milk is higher in those herds that used a bucket milking system rather than a pipeline system. It is also higher in herds fed component feeds, fed leftover feed, fed plastic feed bunks and with a low frequency of feed bunk cleaning. It is lower in herds that practice pre-milking teat disinfection.

Farmers or others who consume raw milk need to be aware of the risk of infection, especially if they fall within at-risk categories. There may be a particular risk with milk from goats and sheep fed silage. People associated with agriculture are also more liable to direct zoonotic transmission of listerial disease. Dentinitis with a papular and pustular rash occurs on the arms of veterinarians following the handling of infected dystocia cases and aborted fetuses. Conjunctivitis is also recorded in agricultural workers handling infected livestock.

Although L. monocytogenes rarely causes disease in pigs it is present in the tonsils and feces of some pigs at slaughter and this presence is a potential source of contamination of the carcass and the slaughterhouse environment. There is a significantly higher prevalence in the tonsils of fattening pigs than in those of sows. The organism can be isolated from the floors, walls, and feed in pig units. Wet feeding, poor hygiene, and a short spelling period between batches of pigs in the finishing house have been found to be risk factors for infection in pigs. Paradoxically, disinfecting the pipeline used for wet feeding was associated with a higher risk of fecal contamination than no disinfection at all.

A further concern for indirect zoonotic risk of L. monocytogenes is the presence of the organism in the feces on infected farms and the potential for fecal or wind-borne dust spread to adjacent fields that may contain crops for human consumption.
PATHOGENESIS
In most animals, ingestion of the organism, with penetration of the mucosa of the intestine, leads to an apparent infection with prolonged febrile excretion of the organism and to a subclinical bacteremia, which clears with the development of immunity. The bacteremic infection is frequently subclinical and may be accompanied by excretion of the organism in milk. Septicemic listeriosis, with or without meningitis, occurs most commonly in neonatal ruminants and in adult sheep and goats, particularly if they are pregnant and when the infection challenge is large.

The organism is a facultative intracellular pathogen that can infect cells, including intestinal cells, by directed endocytosis. It can survive and grow in macrophages and monocytes. Bacterial superoxide dismutase protects against the bactericidal activity of the respiratory burst of the phagocyte and listeriolysin O disrupts lysosomal membranes, allowing the organism to grow in the cytoplasm. The experimental mouse model indicates that cell-mediated immunity is important in protection against listerial infection but studies in goats suggest that the clearance of bacteremic infection and resistance to infection are also strongly associated with humoral antibody.

In pregnant animals invasion of the placenta and fetus may occur within 24 hours of the onset of bacteremia. Edema and necrosis of the placenta leads to abortion, usually 5–10 days postinfection. Infection late in pregnancy results in stillbirths or the delivery of young that rapidly develop a fatal septicemia. Maternal metritis is constant and if the fetus is retained a fatal listerial septicemia may follow. Infection of the uterus causing abortion and intrauterine infection occurs in all mammals.

Encephalitis
Encephalitis in ruminants occurs as an acute inflammation of the brainstem and is usually unilateral. The portal of entry is by ascending infection of the trigeminal or other cranial nerves following loss of the integrity of the buccal mucosa resulting from trauma, the shedding of deciduous or permanent teeth or from periodontitis. Clinical signs are characterized most strongly by an asymmetric disorder of cranial nerve function, and in particular the trigeminal, facial, vestibular, and glossopharyngeal nerves, but there is some variation in the involvement of individual cranial nerves depending upon the distribution of lesions in the brainstem. Lesions in the sensory portion of the trigeminal nucleus and the facial nucleus are common and lead to ipsilateral facial hypalgnesia and paralysis; involvement of the vestibular nucleus is also common and leads to ataxia with circling and a head tilt to the affected side. The additional signs of dullness, head pressing, and delirium are referable to the more general effects of inflammation of the brain developing in the agonal stages. Spread of the infection along the optic nerve may result in endophthalmitis in sheep and cattle.

Spinal myelitis
Spinal myelitis possibly results from ascending infection in the sensory nerves of the skin following dermatitis from prolonged wetting of the fleece.

Mastitis
L. monocytogenes is rarely found to be a cause of mastitis in cattle, despite the fact that it can be common in the dairy environment of herds that have milking practices that could be conducive to the introduction of environmental pathogens into the udder. This suggests that it is not a particularly invasive or perpetuating organism for the udder.

CLINICAL FINDINGS
When disease occurs it is usual to have an outbreak of either encephalitis or abortion. Encephalitis is the most prevalent manifestation in sheep. Septicemia in lambs may occur in conjunction with abortion but it is rare to have all three syndromes on the same farm, at least in the same temporal period. There are always exceptions to such generalities, and the occurrence of septicemia, abortion, and encephalitis in a flock of sheep is possible.

Listerial encephalitis
Sheep
In sheep, early signs are separation from the flock, and depression with a hunched stance. Sheep approached during this early stage show a frenzied desire to escape but are uncoordinated as they run and fall easily. The syndrome progresses rapidly with more severe depression to the point of somnolence and the development of signs of cranial nerve dysfunction. Fever – usually 40°C (104°F) but occasionally as high as 42°C (107°F) – is usual in the early stages of the disease but the temperature is usually normal when overt clinical signs are present.

Signs vary between individual sheep but incoordination, head deviation sometimes with head tilt, walking in circles, unilateral facial hypalgnesia and facial paralysis are usually present. Facial hypalgnesia can be detected by pressure from a hemostat and the facial paralysis is manifest with drooping of the ear, paralysis of the lips and ptosis on the same side of the face as the hypalgnesia. This may be accompanied by exposure keratitis, often severe enough to cause corneal ulceration. Strabismus and nystagmus occur in some. Panophthalmitis, with pus evident in the anterior chamber of one or both eyes, is not uncommon in cattle that have been affected for a number of days. Also there is paresis of the muscles of the jaw, with poor tone or a drooped jaw, in which case prehension and mastication are slow and the animal may stand for long periods drooling saliva and with food hanging from its mouth.

Septicemia
In cattle, the clinical signs are essentially the same but the clinical course is longer. In adult cattle the course of the disease is usually 1–2 weeks but in sheep and calves the disease is more acute, death occurring in 2–4 days.

Goats
In goats the disease is similar to that in the other species, but in the young goat the onset is very sudden and the course short, with death occurring in 2–3 days.

Listerial abortion
Outbreaks of abortion of L. monocytogenes are recorded in cattle but occur more commonly in sheep and in goats. Abortion due to this organism is rare in pigs.

Cattle
In cattle, the clinical signs are essentially the same but the clinical course is longer. In adult cattle the course of the disease is usually 1–2 weeks but in sheep and calves the disease is more acute, death occurring in 2–4 days.

Goats
In goats the disease is similar to that in the other species, but in the young goat the onset is very sudden and the course short, with death occurring in 2–3 days.

Listerial abortion
Outbreaks of abortion of L. monocytogenes are recorded in cattle but occur more commonly in sheep and in goats. Abortion due to this organism is rare in pigs.

Cattle
In cattle, the clinical signs are essentially the same but the clinical course is longer. In adult cattle the course of the disease is usually 1–2 weeks but in sheep and calves the disease is more acute, death occurring in 2–4 days.

Goats
In goats the disease is similar to that in the other species, but in the young goat the onset is very sudden and the course short, with death occurring in 2–3 days.
are low but may reach as high as 15%. On some farms, abortions recur each year.

Abortion due to *Listeria ivanovii*
This occurs as a sporadic disease in cattle and has no distinguishing clinical features from that associated with *L. monocytogenes*.44,47 Outbreaks in sheep are manifest with abortion and stillbirth but particularly with the birth of live infected lambs, which seldom survive long enough to walk or suck.

**Septicemic listeriosis**
Acute septicemia due to *L. monocytogenes* is not predictive in adult ruminants but does occur in monogastric animals, and in newborn lambs and calves. There are no signs suggestive of nervous system involvement, the syndrome being a general one comprising depression, weakness, emaciation, pyrexia, and diarrhea in some cases, with hepatic necrosis and gastroenteritis at necropsy. The same syndrome is also seen in ewes and goats after abortion if the fetus is retained. A rather better defined but less common syndrome has been described in calves 3–7 days old. Corneal opacity is accompanied by dyspnea, nystagmus, and mild opisthotonos. Death follows in about 12 hours. At necropsy there is ophthalmitis and serofibrinous meningitis. Septicemic listeriosis is recorded in a foal.48

**Mastitis**
Infection in the udder may involve a single quarter or both quarters; it is chronic and poorly responsive to treatment. There is a high somatic cell count in milk from the affected quarter, but the milk appears normal.

**Spinal myelitis**
There is fever, ataxia with initial knuckling of the hindlimbs progressing to hindlimb weakness and paralysis. In some cases, both in sheep and cattle, there is also paresis and paralysis of the front limbs. There is no evidence of cranial nerve involvement and affected animals are initially mentally alert, bright and continue to eat. However, there is rapid deterioration and affected animals are commonly humanely destroyed.

**Ophthalmitis, iritis**
There is swelling of the iris and conjunctiva of the pupil; white focal lesions are evident on the internal surface of the cornea with flocular material in the anterior chamber. Advanced cases have pannus and corneal opacity. One or both eyes are affected.

**Enteritis in weaner sheep**
Initially, sheep are found dead. Others in the group show lethargy, anorexia, and pass loose, green-colored feces. Pregnant ewes may abort.

**CLINICAL PATHOLOGY**
The organism can be cultivated from vaginal secretions for up to 2 weeks after abortion and a proportion of aborting animals also have *L. monocytogenes* in the milk and feces.

The cerebrospinal fluid in cases of encephalitis has increased protein and an increased number of leucocytes, most of which are mononuclear cells or lymphocytes.55,56 *L. monocytogenes* is not detectable by culture or PCR.56 Electrodiagnostic examinations are reported.51

Serological tests (agglutination and complement fixation tests) have been used but lack the predictive value required for diagnostic use. Ruminants commonly have antibody to *Listeria* and high titers are commonly encountered in normal animals in flocks and herds where there have been clinical cases. Nucleic-acid-based techniques can be used to determine the source of a strain of *L. monocytogenes* in an outbreak.13

**NECROPSY FINDINGS**
Typically there are no distinctive gross changes associated with listerial encephalitis. Histological examination of central nervous system tissue is necessary to demonstrate the microabscesses that are characteristic of the disease. These are present in the brainstem in listerial encephalitis and in the cervical and/or lumbar spinal cord in outbreaks of spinal myelitis. Sampling of the forebrain will typically result in a false-negative diagnosis. Cold enrichment techniques are advisable when attempting to isolate the organism. Gram staining of paraffin-embedded tissue may permit confirmation of the diagnosis in cases for which suitable culture material is unavailable. Alternative test methods such as fluorescent antibody or immuno-peroxidase tests are available in some laboratories. In one retrospective study comparing diagnostic methods, immuno-peroxidase staining was superior to bac-tidium in the muscosa layer of the abomasum.8

**Samples for confirmation of diagnosis**

- **Central nervous system listeriosis**
  - Bacteriology – half of midsagittally sectioned brain, including brainstem, chilled or frozen (CULT, FAT)
  - Histology – formalin-fixed half of midsagittally sectioned brain, including brainstem; appropriate segment of spinal cord if spinal myelitis suspected (LM, IHC)

- **Septicemia and abortion**
  - Bacteriology – chilled liver, spleen, lung, placenta, fetal stomach content (CULT, FAT)
  - Histology – formalin-fixed liver, spleen, lung, brain, placenta, fetal intestine (LM, IHC)

**DIFFERENTIAL DIAGNOSIS**

- **Encephalitis**
  - Pregnancy toxemia in sheep
  - Nervous ketosis in cattle
  - Rabies
  - Gir
  - Polioencephalomalacia
  - Middle ear disease
  - Scrape
  - Abortion
  - Sheep (Table 18.4)
  - Cattle (Table 18.5)
  - Gastroenteritis
  - Salmonellosis
  - Uveitis
  - Contagious ophthalmia

**TREATMENT**
The intravenous injection of chlortetracycline (10 mg/kg BW per day for 5 d) is reasonably effective in meningoencephalitis of cattle but less so in sheep. Penicillin at a dosage of 44 000 IU/kg BW given intramuscularly daily for 7 days, and in many cases for 10–14 days, can also be used. The recovery rate depends largely on the time that treatment is started after the onset of clinical signs. If severe clinical signs are already evident, death usually follows in spite of treatment. Usually the course of events in an outbreak is that the first case dies but subsequent cases are detected sufficiently early for treatment. Dehydration, acid-base imbalances and electrolyte disturbances must also be corrected. Cases of spinal myelitis are poorly responsive to treatment.

Treatment of listerial iritis is with systemic antibiotics in the early stages coupled with subpalpebral corticosteroid and atropine to dilate the pupil.

In vitro resistance to the tetracycline group of antimicrobials is reported.53

**CONTROL**
Control is difficult because of the ubiquitous occurrence of the organism, the lack
of a simple method of determining when it is present in high numbers in the environment and a poor understanding of the risk factors other than silage. Where the risk factor is silage there may be some merit in the recommendation that a change of diet to include heavy feeding of silage should be made slowly, particularly if the silage is spoiled or if listeriosis has occurred on the premises previously. Tetracyclines can be fed in the ration of animals at risk in a feedlot. When possible, the obviously spoiled areas of silage should be separated and not fed.

Other recommendations on the feeding of silage include avoiding making silage from fields where molehills may have contaminated the grass, avoiding soil contamination when filling the clamp; the use of additives to improve fermentation and the avoidance of silage that is obviously decayed, or with a pH of greater than 5 or an ash content of more than 70 mg/kg of dry matter.

Silage removed from the clamp should be fed as soon as possible. Where uveitis is a problem, feeding systems that avoid eye contact with silage should be used.

A live attenuated vaccine has been shown to induce protection against intravenous challenge and a live attenuated vaccine in use in Norway for several years is reported to reduce the annual incidence of the disease in sheep from 4% to 1.5%. An economic model is available for systems that avoid eye contact with silage contamination when filling the clamp; the avoidance of silage there may be some risk factor is silage. Other recommendations on the feeding of silage include avoiding making silage from fields where molehills may have contaminated the grass, avoiding soil contamination when filling the clamp; the use of additives to improve fermentation and the avoidance of silage that is obviously decayed, or with a pH of greater than 5 or an ash content of more than 70 mg/kg of dry matter.

**REFERENCES**

**ETIOLOGY**

Erysipelothrix rhusiopathiae (insidiosa) is the causative bacterium and the disease can be produced in acute and subacute septicemic and chronic forms by the injection of cultures of the organism. A number of different serotypes have been identified, usually types 1 and 2 in pigs. Many of the serotypes have been regrouped and called Erysipelothrix rhusiopathiae. This is a non-pathogenic type found in the tonsil that is morphologically and biochemically similar to E. rhusiopathiae but has a very distinctive genetic profile. In many minimal disease herds they have tended not to vacinate and then the epizootics have occurred as a result of an increasing lack of immunity.

**EPIDEMIOLOGY**

Occurrence

Erysipelothrix in pigs occurs worldwide and in most countries has reached a level of...
incidence sufficient to cause serious economic loss due to deaths of pigs and dermal ulceration of pig carcasses because of arthritis. An epidemic occurred in the USA in 1989/90. However, since total indoor confinement of swine herds and the lack of contact with contaminated soil has increased, the occurrence of the disease has decreased markedly. The exception to this would be outdoor units where no vaccination is practiced. Historically, the disease occurred most commonly in unvaccinated growing pigs over 3 months of age and adults. This is primarily because the maternal antibody is believed to last up to 3 months. The infection, usually with serotypes 1a or 2, has also been demonstrated in wild boars, so these should not be forgotten as a reservoir. Perhaps more importantly, these were resistant to oxytetracycline and/or dihydrostreptomycin.

Prevalence of infection
The prevalence of infection with E. rhusiopathiae in carrier pigs ranges from 3–98%, with most surveys indicating that 20–40% of pigs are carriers. Carriers occur among vaccinated as well as unvaccinated pigs. The organism has been isolated from 10% of apparently healthy slaughter pigs. This explains why the usual source is other pigs.

Morbidity and case fatality
Morbidity and case fatality rates in pigs vary considerably from area to area, largely because of variations in virulence of the particular strain of the organism involved. On individual farms or in particular areas the disease may occur as a chronic arthritis in finishing pigs, or as extensive outbreaks of the acute septicemia, or both forms may occur together. In unvaccinated pigs, the morbidity in the acute form will vary from 10–30%; the case fatality rate may be as high as 75%.

Methods of transmission
Soil contamination occurs through the feces of affected or carrier pigs. Other sources of infection include infected animals of other species, and birds. The clinically normal carrier pig is the most important source of infection, the tonsils being the predilection site for the organism. Young pigs in contact with carrier sows rapidly acquire the status of carriers and shedders. Since the organism can pass through the stomach without loss of viability, carrier animals may re-infect the soil continuously and this, rather than survival of the organism, appears to be the main cause of environmental contamination. The organism can survive in feces for several months. All effluent contains species of Erysipelothrix but there is no need to assume that it is E. rhusiopathiae. However, its persistence in soil is variable and may be governed by many factors including temperature, pH and the presence of other bacteria. It can survive for 60 months in frozen or refrigerated media, 4 months in flesh and 90 days in highly alkaline soil.

The organism can be isolated from the effluent of commercial piggeries and from the soil and pasture of effluent disposal sites for up to 2 weeks after application of the effluent containing the organism. In a survey of the occurrence of potential pathogens in slurry, the organism was found in samples from 49% of 84 cattle herds, 44% of 32 pig herds and 39% of 67 cattle and pig herds. Although the environment is considered to be secondary to animals as a reservoir of infection, the survival of the organism in the environment could create an infection hazard. Flies are known to transmit the disease and a lowered prevalence has been attributed to the use of insecticides.

Under natural conditions, skin abrasions and the alimentary tract mucosa are considered to be the probable portals of entry and transmission is by ingestion of contaminated feed. Occasional outbreaks occur after the use of virulent and incomplete avirulent culture as vaccines. Abortion storms in late pregnant sows with septicaemic death in sucklers may be the first indication of the disease in specific-pathogen-free herds.

Spread of the infection can also occur to most other species. The organism has been recovered from sylvatic mammals in north-western Canada. It has been isolated from a horse affected with vegetative endocarditis. It has, at times, been found in fish meal but this is now used much less often in pig diets. It is possible that other species, such as cattle, may harbor strains that are pathogenic for swine.

Pathogen risk factors
At least 32 serotypes are known to exist and many strains; however, 15 probably commonly affect pigs. Serotypes 1 and 2 are the most common types isolated from swine affected with clinical erysipelas and are generally believed to be the only serotypes that cause the acute disease. The other serotypes are relatively uncommon and none of them has yet been a cause of acute epidemics, but some have been isolated from lesions of chronic erysipelas. Serotypes 1a, 3, 5, 6, 8, 11, 21, and type N have been isolated from pigs with chronic erysipelas, mainly arthritis and lymphadenitis. In the USA, 19 of the 22 serotypes have been found and the most frequent are serotypes 1, 2, 5, 6, and 21.

Not all serotypes isolated from pigs are virulent. In a survey in Japan, the organism was found in 10% of the tonsils of healthy slaughter pigs: 54% were serotype 7, 32% serotype 2, 9.5% serotype 6 and 1.6% each of serotypes 11, 12, and 16. All serotype 2 isolates were highly virulent for pigs while the other serotypes were only weakly virulent. Members of the other nonvirulent or weakly virulent group, mainly serotype 7 strains, are considered to be resident in porcine tonsils. Serotypes 1 (subtypes 1a and 1b), 2, 5, 6, and 4 have been found in Puerto Rico. Serotypes 1a or 2 were found most commonly in pigs in Australia, less commonly in sheep and infrequently in other animals. Serotypes 1a and 1b accounted for 79% of the isolates from diseased pigs. A cluster of avirulent strains of serotype 7 from the tonsils of pigs has been identified as E. tonsillarum. The genetic diversity of Australian field isolates of E. rhusiopathiae and E. tonsillarum indicates widespread diversity. Those recovered from sheep or
birds were more diverse than those isolated from pigs, and isolates of serovar 1 were more diverse than those of serovar 2. The diversity indicated that serotyping of *E. rhusiopathiae* is unreliable as an epidemiological tool.20

The relatedness of the isolates tested by DNA fingerprinting suggests that *E. tollsarium* contains the former serotypes 3, 7, 10, 14, 20, 22, and 23, with serotypes 13 and 18 intermediate between this species and *E. rhusiopathiae*. *E. rhusiopathiae* represents serotypes 1, 2, 4, 5, 6, 8, 9, 11, 12, 15, 16, 17, 19, 21, and N. Some serotypes shown to be *E. tollsarium* on serological grounds have been found to be *E. rhusiopathiae* on enzyme analysis. The serotype antigens of *E. rhusiopathiae* (insidiosa) are immunologically distinct, and commercial bacterins prepared from the common serotypes will not provide protection against other pathogenic serotypes. This may be an explanation for the epidemics that may occur in vaccinated pigs. The 64–66 kDa protein appears to be most immunogenic.21 Also, a variety of serotypes may be recovered from pigs affected with the septicemic and arthritic forms of the disease.

The organism is resistant to most environmental influences, and to heat (15 min at 60°C) and can survive in animal tissues at 40°C and frozen tissues and is not readily destroyed by chemical disinfection, including 0.2% phenol and by drying agents.

### Zoonotic implications

Because of humans’ susceptibility, swine erysipelas has some public health significance.22 Veterinarians in particular are exposed to infection when vaccinating with virulent culture. It commonly contaminates pig products and therefore is most immunogenic. Also, a variety of serotypes may be recovered from pigs affected with the septicemic and arthritic forms of the disease.

The organism is resistant to most environmental influences, and to heat (15 min at 60°C) and can survive in animal tissues at 40°C and frozen tissues and is not readily destroyed by chemical disinfection, including 0.2% phenol and by drying agents.

### PATHOGENESIS

The invasion of the susceptible pig by *E. rhusiopathiae* can occur under particular circumstances, i.e. if weather conditions are hot and humid or in particular fields or buildings. Experimentally, it is often easier to infect the pig through скафид wounds than through intravenous infections.

No specific virulence factors have been found but there is the presence in the pathogenic serotypes of an ability to produce a capsule that resists phagocytosis.27 Some others may produce a neuraminidase, which may cleave the mucopoly-saccharides in cell walls and cause vascular damage leading to hemorrhage and thrombosis. Invasion of the bloodstream occurs in all infected animals in the first instance. Septicemia results within 1–7 days. The subsequent development of either an acute septicemia or a bacteremia with localization in organs and joints is dependent on undetermined factors. Virulence of the particular strain may be important and this may depend upon the number of recent pig passages experienced. Coagulase activity is a possible virulence factor.28 Current viral infection, especially hog cholera, may increase susceptibility of the host.

Localization in the chronic form is common in the skin and joints, and on other heart valves, with probable subsequent bacteremic episodes, and it may start from as early as 4 days after initial infection, although the cartilage lesions may be delayed until about 8 months and they can then continue to progress for at least 2 years. Selective adherence of some strains of *E. rhusiopathiae* (insidiosa) to heart valves may be a factor in the pathogenesis of endocarditis.29 In joints, the initial lesion is an increase in synovial fluid and hyperemia of the synovial membrane, followed in several weeks by the proliferation of synovial villi (really a synovitis), thickening of the joint capsule and enlargement of the local lymph nodes. Diskospondylitis also occurs in association with chronic polyarthritis due to *E. rhusiopathiae*.30 Amyloidosis may occur in pigs with chronic *E. rhusiopathiae* polyarthritis.31 The heart lesions may begin with early inflammatory changes associated with emboli.

There has been some controversy over whether the arthrodial lesions result from primary infection or whether they result from hypersensitivity to the *Erysipelothrix* or other antigen. Current opinion suggests that the former is the case but that the lesions are enhanced by immunological mechanisms to persistent antigen at the site. There are increased levels of immunoglobulins IgG and IgM in the synovial fluids of pigs with polyarthritis due to *E. rhusiopathiae* (insidiosa)32 and the levels are considered only partly due to serum and increased permeability.

Experimentally the disease can be produced by oral dosing, by intradermal, intravenous, and intra-articular injection, and by application to scarified skin, conjunctiva, and nasal mucosa. The arthritic form of the disease can be reproduced by multiple intravenous inoculations of *E. rhusiopathiae*.33

The microscopic lesions include vascularitis in capillaries and venules in many sites, including glomeruli, pulmonary capillaries, and the skin. Sometimes, it is possible to see emboli of bacteria without specific stains to demonstrate bacteria.

### CLINICAL FINDINGS

#### Hyperacute form

Quite often the disease is seen for the first time in pigs approaching market weight. The animal is dead or dull, depressed and with a temperature of 42°C (108°F), which is followed soon after by severe prostration, complete anorexia, thirst and occasional vomiting. Initially, affected pigs may be quite active and continue to eat even though their temperatures are high. However, generally in an outbreak one is initially presented with one or two dead or severely affected pigs showing marked red to purple discoloration of the skin of the paws and ventral surface (may even be whole-body cyanosis), with others in the group showing high fever, reluctance to rise and some incoordination while walking. Dyspnea is a common feature. A conjunctivitis with ocular discharge may be present. Acute nonfatal erysipelas in sows was described recently in the USA.34 In this outbreak the sows were pyrexic, lethargic, lame, and had multiple erythematous plaques.

Skin lesions are almost pathognomonic but may not always be apparent. These may take the form of the classical diamond-shaped, red, urticarial plaques about 2.5–5 cm square or a more diffuse edematous eruption with the same appearance. In the early stages the lesions are often palpable before they are visible. The lesions are most common on the belly, inside the thighs and on the throat, neck, and ears, and usually appear about 24 hours after the initial signs of illness. Sometimes they can be felt rather than seen. After a course of 2–4 days the pig recovers or dies, with diarrhea, dyspnea, and cyanosis evident terminally. The mortality rate may reach 75% but wide variation occurs. Pregnant animals may abort and it is thought that this is due to the fever but it may be that there is a direct fetal action, as congenital infections and isolations of the organism from the fetus have occurred.

The so-called ‘skin’ form is usually the acute form with more prominent skin localization but less severe signs of septicemia and with a low mortality. The skin lesions disappear in about 10 days without residual effects. In the more serious cases the plaques spread and coalesce, often over the back, to form a clinic research article on the unit health and how did the pigs behave.
Diseases associated with Erysipelothrix rhusiopathiae (insidiosa)

Continuous, deep purple area extending over a greater part of the skin surface. The affected skin becomes black and hard, and the edges curl up and separate from an underlying, raw surface. The dry skin may hang on for a considerable time and rattle while the pig walks, or it may slough off.

**Chronic form**

Signs are vague and indistinct except for the joint lesions characteristic of this form of the disease. There may be alopecia, sloughing of the tail and tips of the ears, and a dermatis in the form of hyperkeratosis of the skin of the back, shoulders, and legs; growth may be retarded. Joint lesions are commonest in the elbow, hip, hock, stifle, and knee joints and cause lameness and stiffness. The joints are obviously enlarged and are usually hot and painful at first but in 2–3 weeks are quite firm and without heat. This is especially the case when the arthritis has been present for some time, allowing healing and ankylosis to develop. Paraplegia may occur when intervertebral joints are involved or when there is gross distortion of limb joints.

A subclinical form of synovitis may occur which affects feed intake and results in a reduced rate of growth.

Endocarditis also occurs as a chronic form of the disease with or without arthritis. Suggestive clinical signs are often absent, the animals dying suddenly without previous illness, especially at times of exertion such as mating, or movement between pens. In others there is progressive emaciation and inability to perform exercise. With forced exercise dyspnea, cyanosis and even sudden death may occur. The cardiac impulse is usually markedly increased, the heart rate is faster, and a loud murmur is audible on auscultation if the valves are badly damaged.

In Switzerland, they suspect chronic swine erysipelas in herds where there is vegetative endocarditis, arthritis and the culture of *E. rhusiopathiae* from vulval discharges. These signs are also accompanied by poor fertility and increased prevalence of abortions, stillbirths and small litter size. The same authors describe the use of vaccine to control an outbreak of purulent periarticular vulval discharge in which *E. rhusiopathiae* was the only organism isolated. In one of their studies anterior vaginal samples from 64 sows all yielded *E. rhusiopathiae*.

**CLINICAL FINDINGS**

**Detection of organism**

In the acute form, examination of blood smears may reveal the presence of the bacteria, particularly in the leukocytes, but blood culture is likely to be more successful as a method of diagnosis. Repeated examinations in the chronic forms of the disease may by chance give a positive result during a bacteremic phase. Final identification of the organism necessitates mouse or pigeon inoculation tests, and protection tests in these animals using anti-erysipelas serum.

**Hematology**

In the early stages of the acute form there is first a leukocytosis followed by a leukopenia and a monocytosis. The leukopenia is of moderate degree (40% reduction in total leukocyte count at most) compared with that occurring in hog cholera. The monocytosis is quite marked, varying from a fivefold to a tenfold increase (2.5–4.5% normal levels rise to 25%).

**Serology**

The efficiency of agglutination tests for *E. rhusiopathiae* (insidiosa) is not clear. They appear to be satisfactory for herd diagnosis but not sufficiently accurate for identification of individual affected pigs, particularly clinically normal carrier animals. A more accurate complement fixation test is available but an enzyme immunoassay test is much quicker, easier and more economical to perform. An ELISA test has been used to measure the serological response of experimentally induced erysipelas arthritis in pigs and 65kDa antigen from the organism is being evaluated as an antigen agent. Complement fixation tests may be more reliable.

**NECROPSY FINDINGS**

**Acute form**

In the hyperacute cases all that may be seen is a congested carcass with discoloration of the skin. The degree of skin discoloration may provide a clue to prognosis, in that it is said that if the skin lesions are pink to light purple then resolution will often occur within 4–7 days but the dark angry black/purple lesions have a grave prognosis.

Classic ‘diamond skin’ lesions may be present. However, the diffuse, purplish discoloration of the belly and cyanosis of the extremities common to other septicemic diseases of pigs is a more reliable finding. Internally, petechial and ecchymotic hemorrhage occurs, mainly on the pleura and peritoneum and beneath the renal capsule but also on the heart, liver, and spleen. Venous infarction of the stomach is accompanied by swollen, hemorrhagic mesenteric lymph nodes and there is congestion of the lungs and liver. Infarcts may be present in the spleen and kidney and the former much enlarged. Histological changes in all tissues are those of toxemia and thrombosis. Large numbers of intravascular organisms are often visible. There are no specific histological changes.

**Chronic form**

A nonsuppurative proliferative arthritis involving limb and intervertebral joints is characteristic. A synovitis, with a serous or serofibrinous amber-colored intra-articular effusion occurs first and degenerative changes in the subendochondral bone, cartilage and ligaments follow. When the synovial changes predominate, the joint capsule and villi are thickened. There are enlarged, dark red pedunculations or patches of vascular granulation tissue, which spread as a pannus on to the articular surface. When bony changes predominate, the articular cartilage is detached from the underlying bone, causing abnormal mobility of the joint. Ulceration of the articular cartilage may also be present. Local lymph node enlargement is usual. With time, the joint lesions often repair by fibrosis and ankylosis sufficiently to permit use of the limb.

Endocardial lesions, when present, are large, friable vegetations on the valves, often of sufficient size to block the valvular orifice. Occasionally, endocarditis may be the only lesion seen but this is a rare occurrence. Erysipelas is often said to rank below *S. suis* as a cause of endocarditis in growing pigs but *E. rhusiopathiae* (insidiosa) was the most frequent isolate from cases of endocarditis seen in slaughtered pigs. Infarcts occur in the kidney and these may also yield pure cultures of the organism. Chronic joint lesions are often sterile but bacteriological culture should nevertheless be attempted. The probability of positive isolation increases with the number of joints sampled, and isolations are more frequent from the smaller, distal joints.

Enrichment techniques and the use of selective media will also increase the frequency of isolation of *E. rhusiopathiae* (insidiosa).

**Samples for confirmation of diagnosis**

From acute cases includes:

- Bacteriology – culture swabs from joints; synovial membranes in culture media, heart valve masses, spleen, kidney, and bone marrow, particularly from a long bone. Smears of heart blood are particularly useful in the first 1–2 days of the acute diseases. The organism is a slender, facultatively anaerobic, Gram-positive rod that produces a 1 mm gray colony after 24 hours incubation on blood agar. It may be observed singly, in short chains or as a palisade. Different morphological types (rough and smooth colonies) exist and the rough are considered less virulent. Bacteriological examination of subacute cases is less successful and chronic cases not successful. Florescent techniques have been developed to show antigen in joints.

DIAGNOSIS
Clinical signs, isolation of the agent from multiple sites including blood in the acute stages; but diagnosis from joints in chronic stages is more difficult.

DIFFERENTIAL DIAGNOSIS
Erysipelas in pigs is not ordinarily difficult to diagnose because of the characteristic clinical and necropsy findings. In the occasional situation where anthrax may have occurred in the past it is worth testing a smear of edema fluid taken by a needle from the jowl or ear region for this pathogen. The acute disease may be confused with the other septicemias affecting pigs, but pigs with erysipelas usually show the characteristic skin lesions and are less depressed than pigs with hog cholera or salmonellosis.

Other septicemias of pigs
- Septicemic salmonellosis is characterized by gross blue-purple discoloration of the skin, especially the ears, some evidence of enteritis, and polyneuritis and dyspnea.
- Hog cholera is characterized by large numbers of pigs affected quickly, weakness, fever, muscle tremors, skin discoloration and rapid death; convulsions are also common.
- Streptococcal septicaemia and arthritis are almost entirely confined to suckling pigs in the first few weeks of life as it is septicaemia associated with Actinobacillus suis.
- Streptococcal endocarditis has a similar age distribution to erysipelas and bacteriological examination is necessary to differentiate them.

Other arthritides of pigs
The chronic disease characterized by joint disease occurs in pigs of all ages but less commonly in adults and must be differentiated from the following conditions:
- Glasser’s disease in pigs is accompanied by a severe painful dyspnea. At necropsy there is seborrhoea and meningitis.
- Mycoplasma arthritis generally affects pigs less than 10 weeks of age and produces a polyarthritis as well as polyarthritis. However, Mycoplasma hyosynoviae can produce simple polyarthritis in growing pigs. In general the periarthritis, synovial, and cartilaginous changes are less severe in these infections when compared to erysipelas; however, cultural differentiation is frequently necessary.

- Rickets and chronic zinc poisoning produce lameness in pigs but they occur under special circumstances, are not associated with fever, and rickets is accompanied by abnormalities of posture and gait that are not seen in erysipelas.
- Foot rot of pigs is easily differentiated by the swelling of the hoof and the development of discharging sinuses at the coronet.
- Leg weakness. In recent years there has been a marked increase in chronic osteoarthritis and various forms of ‘leg weakness’ in growing swine, probably related to the increased growth rate resulting from modern feeding and management practices.

TREATMENT
Antimicrobial therapy
Penicillin and anti-erysipelas serum comprise the standard treatment, often administered together by dissolving the penicillin powder in the serum. Penicillin alone is usually adequate when the strain has only mild virulence. Standard dose rates give a good response in the field but experimental studies suggest that 50,000 IU/kg BW of procaine penicillin intramuscularly for 3 days are required for complete chemotherapeutic effect. Most animals are significantly improved within 2 days. Octreotide is also useful.¹⁰ Chronic cases do not respond well to either treatment because of the structural damage that occurs to the joints and the inaccessibility of the organism in the endocardial lesions. Most strains are resistant to apramycin, neomycin, streptomycin, and spectinomycin and also sulfonamides and polymyxins.

CONTROL
Successful control depends on good hygiene, biosecurity (other pigs and other species), reduction of stress, an effective 6-monthly vaccination policy, preferably two doses, for all animals including boars over 3 months of age, as well as rapid diagnosis, quarantine, and treatment.

Eradication
Eradication is virtually impossible because of the ubiquitous nature of the organism and its resistance to adverse environmental conditions. Complete removal of all pigs and leaving the pens unstocked is seldom satisfactory. Eradication by slaughter of reactors to the agglutination test is not recommended because of the uncertain status of the test.

General hygienic precautions should be adopted. Clinically affected animals should be disposed of quickly and all introductions should be isolated and examined for signs of arthritis and endocarditis. This procedure will not prevent the introduction of clinically normal carrier animals. All animals dying of the disease should be properly incinerated to avoid contamination of the environment. Although thorough cleaning of the premises and the use of very strong disinfectant solutions is advisable, these measures are unlikely to be completely effective. The organism is susceptible to all the usual disinfectants, particularly caustic soda and hypochlorites. Whenever practicable, contaminated feedlots or paddocks should be cultivated.

Specific-pathogen-free pigsties established on virgin soil may remain clinically free of erysipelas for several years. However, because of the high risk of introduction of the organism, it is advisable to vaccinate routinely.

Immunization
Because of the difficulty of eradication, biological prophylactic methods are in common use. Immunizing agents available include hyperimmune serum and vaccines.

Anti-erysipelas serum
The parenteral administration of 5–20 mL of serum, the amount depending on age, will protect in-contact pigs for a minimum of 1–2 weeks, possibly up to 6 weeks, during an outbreak. Suckling pigs in herds where the disease is endemic should receive 10 mL during the first week of life and at monthly intervals until they are actually vaccinated, which can be done as early as 6 weeks provided the sows have not been vaccinated. Repeated administration of the serum may cause anaphylaxis because of its equine origin. For this reason, it has been withdrawn from sale in many countries.

Vaccination
There is no fully satisfactory vaccine available for erysipelas because of the strain variation and short duration of immunity but the vaccines have reduced the occurrence of clinical disease.⁴ Regular administration at 6-monthly intervals overcomes this to some extent but there is always the possibility of a new strain appearing. Vaccines containing serotypes 2 and 10 protect against both Erysipelothrix species.⁴³ Serum-simultaneous vaccination has been largely replaced by the use of bacterins, for which lysozyme and absorbate preparations are available, or by the use of attenuated or avirulent live-culture vaccines, which are administered orally or by injection. The use of live-culture vaccines is prohibited in many countries because of the risk of variation in virulence of the strains used and the possibility of spreading infection.

None of these vaccines gives lifelong protection from a single vaccination, and the actual duration of protection achieved following vaccination varies considerably. You should not assume that protection lasts longer than 6 months. The recent
Vaccination is subcutaneous in the skin behind the ear, or the axilla and the flank. Reactions at the site of injection are not uncommon. Swelling with subsequent nodule formation and occasional abscessation may occur following the injection of bacterins, and modified live vaccines may produce hemorrhage in the skin at the injection site. Granulomatous lesions may occur following the use of oil-based vaccines. There is little evidence that vaccination increases the incidence of arthritis. It has been suggested by a very limited study that maternal antibody does not appear to interfere with the vaccination. These vaccines were also used in pigs with PRRS and found to be safe and effective. In those cases where the vaccine has not worked it may be that the correct serotype was not in the vaccine or the administration and storage instructions were not followed.

ETIOLOGY

Bacillus anthracis is the specific cause of the disease, and pathogenic strains have plasmid-encoded virulent factors: a poly-D-glutamic capsule, which aids in resistance to phagocytosis and is encoded by virulence plasmid pX02, and a tripartite toxin comprised of edema (factor I) lethal (factor II) and protective antigen (factor III) encoded by plasmid pX01. Both plasmids are required for full virulence and avirulent strains occur. There is little diversity among isolates of B. anthracis but genotyping can be used for epidemiological studies. The organism forms spores that persist in the environment for decades.

EPIDEMIOLOGY

Occurrence

The disease probably originated in sub-Saharan Africa and has spread to have a worldwide distribution, although the area prevalence varies with the soil, the climate and the efforts put into suppressing its occurrence. It is often restricted to particular areas, the so-called ‘anthrax belts’, where it is enzootic.

Currently, the characteristic epidemiology of anthrax in developed countries is the occurrence of multicentric foci of infection. Many sudden deaths occur without observed illness, in areas that have recently had appropriate climatic conditions and in which the disease has occurred as long ago as 30 years previously.

In tropical and subtropical climates with high annual rainfalls, the infection persists in the soil, so that frequent, serious outbreaks of anthrax are commonly encountered. In some African countries the disease occurs every summer and reaches a devastating occurrence rate in years with a heavy rainfall. Wild fauna – including hippo, cape buffalo, and elephants – die in large numbers. It is probable that predators act as inert carriers of the infection.

In temperate, cool climates only sporadic outbreaks derive from the soil-borne infection. Accidental ingestion of contaminated bone meal or pasture contaminated by tannery effluent are more common sources. In this circumstance outbreaks are few and the number of animals affected is small. The development of an effective livestock vaccine coupled with the use of penicillin and the implementation of quarantine regulations has caused a marked decline in the occurrence of anthrax in most countries compared to its historical incidence.

Source of the infection

B. anthracis can infect animals directly from the soil or from fodder grown on infected soil, from contaminated bone meal or protein concentrates, or from infected excreta, blood, or other discharges from infected animals. The initial source is often from old anthrax graves where the soil has been disturbed. Spread of the organism within an area may be accomplished by streams, insects, dogs, feral pigs, and other carnivores, and by fecal contamination from infected animals and birds. Avian scavengers such as gulls, vultures, and ravens can carry spores over considerable distances and the feces of carrion-eating birds can contaminate waterholes. Infected wildlife are also a source for domestic animals on common grazing land.

Introduction of infection into a new area is usually through contaminated animal products such as bone meal, fertilizers, hides, hair and wool, or by contaminated concentrates or forage. In recent times as many as 50% of consignments of bone meal imported into the UK have been shown to be contaminated with the anthrax bacillus. Outbreaks in pigs can usually be traced to the ingestion of infected bone meal or carcasses. Water can be contaminated by the effluent from tanneries, from infected carcasses and by flooding and the deposition of anthrax-infected soil.

An outbreak of anthrax has been recorded following the infection of infected blood for the purpose of immunization against anaplasmosis. There have been a number of reports of the occurrence of anthrax following vaccination, probably as a result of inadequately attenuated spores. Wound infection occurs occasionally.

Transmission of the infection

Infection gains entrance to the body by ingestion, inhalation, or through the skin. While the exact mode of infection is often in doubt, it is generally considered that most animals are infected by the ingestion of contaminated food or water. It is true that experimental transmission by this means has not always been successful. Injury to the mucous membrane of the digestive tract will facilitate infection but there is little doubt that infection can take place without such injury. The increased incidence of the disease on sparse pasture is probably due both to the ingestion of contaminated soil and to injury to the oral mucosa facilitating invasion by the organism.

Inhalation infection is thought to be of minor importance in animals, although the possibility of infection through contaminated dust must always be considered. 'Woolsorter's disease' in humans is due to inhalation of anthrax spores by workers in the wool and hair industries, but even in these industries cutaneous anthrax is more common.

Biting flies, mosquitoes, ticks, and other insects have often been found to harbor anthrax organisms and the ability of some to transmit the infection has been demonstrated experimentally. However, there is little evidence that they are important in the spread of naturally occurring disease, with the exception of tabanid flies. The transmission is mechanical only and a local inflammatory reaction is evident at the site of the bite. The tendency, in infected districts, for the heaviest incidence to occur in the late summer and autumn may be due to the increase in the fly population at that time but an effect of higher temperature on vegetative proliferation of B. anthracis in the soil is more likely.

Risk factors

Host risk factors

The disease occurs in all vertebrates but is most common in cattle and sheep and less frequent in goats and horses. Humans occupy an intermediate position between this group and the relatively resistant pigs, dogs, and cats. In farm animals, the disease is almost invariably fatal, except in pigs, and even in this species the case fatality rate is high.

Algerian sheep are said to be resistant and, within all species, certain individuals seem to possess sufficient immunity to resist natural exposure. Whether or not this immunity has a genetic basis has not been determined. The most interesting example of natural resistance is the dwarf pig, in which it is impossible to establish the disease. Spores remain in tissues ungerminated and there is complete clearance from all organs by 48 hours. The ability to prevent spore germination appears to be inherited in this species.

Environment risk factors

Outbreaks originating from a soil-borne infection always occur after a major climate change, for example heavy rain after a prolonged drought, or dry summer months after prolonged rain, and always in warm weather when the environmental temperature is over 15°C (60°F). The hypothesis that these climatic conditions lead to sporulation and vegetative proliferation with the production of incubator areas for anthrax in the soil appears improbable, but spores have a high buoyant density and in wet soils could become concentrated and remain suspended in standing water with further concentration on the soil surface as the water evaporates. This relationship to climate has made it possible to predict 'anthrax years'.

Other risk factors in the environment include close grazing of tough, scratchy feed in dry times, which results in abrasions of the oral mucosa, and confined grazing on heavily contaminated areas around water holes. Some genotypes appear to persist better in calcium-rich soils and organic soils and poorly drained soils have risk in endemic areas.
PATHOGENESIS

Upon ingestion of the spores, infection may occur through the intact mucous membrane, through defects in the epithelium around erupting teeth, or through scratches from tough, fibrous food materials. The organisms are resistant to phagocytosis, in part due to the presence of the poly-D-glutamic acid capsule, and proliferate in regional draining lymph nodes, subsequently passing via the lymphatic vessels into the bloodstream; septicemia, with massive invasion of all body tissues, follows. B. anthracis produces a lethal toxin that causes edema and tissue damage, death resulting from shock and acute renal failure and terminal anoxia.

In pigs, localization occurs in the lymph nodes of the throat after invasion through the upper part of the digestive tract. Local lesions usually eventually lead to a fatal septicemia.

CLINICAL FINDINGS

The incubation period after field infection is not easy to determine but is probably 1–2 weeks.

Cattle and sheep

Only two forms of the disease occur in these species, the peracute and the acute.

The peracute form of the disease is most common at the beginning of an outbreak. The animals are usually found dead without premonitory signs, the course being probably only 1–2 hours, but fever, muscle tremor, dyspnea, and congestion of the mucosae may be observed. The animal soon collapses, and dies after terminal convulsions. After death, discharges of blood from the nostrils, mouth, anus, and vulva are common.

The acute form runs a course of about 48 hours. Severe depression and listlessness are usually observed first, although they are sometimes preceded by a short period of excitement. The body temperature is high, up to 42°C (107°F), the respiration rapid and deep, the mucosae congested and hemorrhagic, and the heart rate much increased. No food is taken and ruminal stasis is evident. Pregnant cows may abort. In milking cows the yield is greatly reduced, milk may be bloodstained or deep yellow in color. Milk from affected animals is unfit for human consumption and is preferably distanced.

In pigs, localization occurs in the lymph nodes of the throat, sternum, perineum, and flanks may occur.

Pigs

In pigs anthrax may be acute or subacute. There is fever, with dullness and anorexia, and a characteristic inflammatory edema of the throat and face. The swellings are hot but not painful and may cause obstruction to swallowing and respiration. Bloodstained froth may be present at the mouth when pharyngeal involvement occurs. Petechial hemorrhages are present in the skin, and when localization occurs in the intestinal wall there is dysentery, often without edema of the throat. A pulmonary form of the disease has been observed in baby pigs that inhaled infected dust. Lobar pneumonia and exudative pleurisy were characteristic. Death usually occurs after a course of 12–36 hours, although individual cases may linger for several days.

Horses

Anthrax in the horse is always acute but varies in its manifestations with the mode of infection. When infection is by ingestion there is septicemia with enteritis and colic. When infection is by insect transmission, hot, painful, edematous, subcutaneous swellings appear about the throat, lower neck, floor of the thorax and abdomen, prepuce, and mammary gland. There is high fever and severe depression and there may be dyspnea due to swelling of the throat or colic due to intestinal irritation. The course is usually 48–96 hours.

CLINICAL PATHOLOGY

Hematology and blood chemistry examinations are not conducted because of the risk for human exposure. In the living animal the organism may be detected in a stained smear of peripheral blood. The reference standard for diagnosis is the detection, by microscopic examination, of a clearly defined metachromatic capsule on square-ended bacilli (often in chains) in a blood smear stained with aged polychrome methylene blue. The blood should be carefully collected in a syringe to avoid contamination of the environment. When local edema is evident smears may be made from aspirated edema fluid or from lymph nodes that drain that area. For a more certain diagnosis, especially in the early stages when bacilli may not be present in the bloodstream in great numbers, blood culture or the injection of syringe-collected blood into guinea-pigs is satisfactory.

Fluorescent antibody techniques are available for use on blood smears and tissue sections. Monoclonal antibodies are also used to provide specific identification of anthrax organisms.

As the carcass decomposes and the vegetative forms of B. anthracis die, diagnosis by smear or culture is more difficult and an immunochromatographic test for protective antigen has been developed that has high specificity and does not give positive results in recently vaccinated cattle. In cases where antibiotic therapy has been used, the identification from blood smears or culture may be difficult and animal passage may be necessary. Isolation of anthrax bacilli from infected soil is difficult, but a real-time quantitative PCR with high sensitivity has been described.
Necropsy findings

There is a striking absence of rigor mortis and the carcass undergoes gaseous decomposition, quickly assuming the characteristic "swallow's" posture. All natural orifices usually exude dark, tarry blood that does not clot. If there is a good reason to suspect the existence of anthrax the carcass should not be opened. If a necropsy is carried out, the failure of the blood to clot, widespread ecchymoses, bloodstained serous fluid in the body cavities, severe enteritis and splenomegaly are strong indications of the presence of anthrax. The enlarged spleen is soft, with a consistency likened to 'blackberry jam'. Subcutaneous swellings containing gelatinous material, and enlargement of the local lymph nodes are features of the disease in horses and pigs. Lesions are most frequently seen in the soft tissues of the neck and pharynx in these species.

To confirm the diagnosis on an unopened carcass, peripheral blood or local edema fluid should be collected by needle puncture. Since the blood clots poorly, jugular venipuncture may permit sample collection. Smears prepared from these fluids should be stained with polychrome methylene blue and examined (see Clinical pathology, above). These fluid samples can also be used for bacteriological culture if smear results are equivocal. The smears should be prepared and interpreted by an experienced and qualified microbiologist.

If decomposition of a carcass is advanced, a small quantity of blood may be collected from the fresh surface of an amputated tail or ear. A portion of spleen is the specimen of choice for bacteriological culture if the carcass has been opened. An immunofluorescence test is available but cross-reactivity with other Bacillus spp. makes its use impractical. An immunochromatographic test that has high specificity for protective antigen has been developed for use in decomposed carcasses.17

The Ascoli test can be used to demonstrate antigen in severely decayed tissue samples and a nested PCR technique has been used to demonstrate antigen in environmental samples.19 PCR methods can also be used to confirm the identity of bacterial isolates. If other detection methods fail, experimental animal inoculation can be attempted. Immunohistochemical detection of the bacilli in skin biopsies of cutaneous anthrax in humans has been described.20 This technique may be useful in retrospective analyses of suspect cases if suitable fresh tissue samples were not collected.

Anthrax is a reportable disease in many countries, requiring the involvement of government regulatory agencies when the disease is suspected or when the diagnosis is confirmed. Representatives of these agencies can often facilitate sample collection and transportation to an appropriate laboratory. If anthrax is suspected, then shipping diagnostic samples via the mail or courier systems is strongly discouraged. Instead, samples should be appropriately packed, labeled and transported directly to the laboratory by one of the staff members of the veterinary clinic. In some countries it may be illegal to send material such as anthrax through the mail system.

Samples for confirmation of diagnosis

- Bacteriology - unopened carcass: blood or edema fluid in sealed, leakproof container; opened carcass: above samples plus spleen (local lymph nodes in horses, pigs) in sealed, leakproof containers (direct smear, CULT, bioassay)
- Histology - formalin-fixed spleen/local lymph nodes if carcass has been opened (LM).

Note the zoonotic potential of this organism when handling carcass and submitting specimens.

Differential diagnosis

There are many causes of sudden death in farm animals and differentiation is often difficult. Diseases where there can be multiple deaths suggestive of anthrax include:

- Lightning strike
- Peracute blackleg
- Malignant edema
- Bacillary hemoglobinuria
- Hypomagnesemic tetany

Treatment

Severely ill animals are unlikely to recover in the early stages, particularly when fever is detected before other signs are evident, recovery can be anticipated if the correct treatment is provided. Penicillin (20 000 IU/kg BW twice daily) has had considerable vogue, but streptomycin (8-10 g/d in two doses intramuscularly for cattle) is much more effective. Oxytetracycline (5 mg/kg BW per day) parenterally has also proved superior to penicillin in the treatment of clinical cases after vaccination in cattle and sheep. Antiserum, if available, should also be administered for at least 5 days in doses of 100-250 mL daily but it is expensive.

In vitro studies show all isolates to be susceptible to ampicillin, streptomycin, erythromycin, tetracycline, methicillin, and netilmicin.14 It is desirable to prolong treatment to at least 5 days to avoid a recrudescence of the disease.

Control

The control of meat- and milk-producing animals in infected herds in such a way as to avoid any risk to the human population is a special aspect of the control of anthrax. It is necessary at the same time to avoid unnecessary waste and the imposition of unnecessarily harsh restrictions on the farmer. When an outbreak occurs, the placing of the farm in quarantine, the destruction of discharges and cadavers, and the vaccination of survivors, are part of the animal disease control program and indirectly reduce human exposure. Prohibition of movement of milk and meat from the farm during the quarantine period should prevent entry of the infection into the human food chain. Vaccination of animals, although the vaccine is a live one, does not present a hazard to humans, although there is a withholding period for meat and milk after its use.

Disposal of infected material is most important and hygiene is the single most important factor in the prevention of spread of the disease. Infected carcasses should not be opened but immediately burned in situ or buried, together with bedding and soil contaminated by discharges. If this can not be done immediately, a liberal application of 5% formaldehyde on the carcass and its immediate surroundings will discourage scavengers. Burning is the preferred method of disposal. Approximately one cord of wood is required to effectively incinerate the carcass of a mature cow. Bags of charcoal briquettes have also been used.2

Burial should be at least 2 m deep with an ample supply of quicklime added. All suspected cases and in-contact animals must be segregated until cases cease and for 2 weeks thereafter the affected farm must be kept in quarantine to prevent the movement of livestock. The administration of hyperimmune serum to in-contact animals may prevent further losses during the quarantine period, but prophylactic administration of a single dose of long-acting tetracycline or penicillin is a much more common practice.

Disinfection of premises, hides, bones, meal, fertilizer, wool, and hair requires special care. When disinfection can be carried out immediately, before spore formation can occur, ordinary disinfectants or heat (60°C (140°F) for a few minutes) are sufficient to kill vegetative forms. This is satisfactory when the necropsy room or abattoir floor is contaminated. When spore formation occurs (i.e. within a few hours of exposure to the air), disinfection is almost impossible by ordinary means. Strong disinfectants such as 5% Lysol require to be in contact with spores for at least 2 days. Strong solutions of formalin or sodium hydroxide (5-10%) are probably most effective. Peracetic acid (3% solution) is an effective...
effective sporicide and, if applied to the soil in appropriate amounts (8 L/m²), is an effective sterilant. Infected clothing should be sterilized by soaking in 10% formaldehyde. Shoes may present a difficulty and sterilization is most efficiently achieved by placing them in a plastic bag and introducing ethylene oxide. Contaminated materials should be damp and left in contact with the gas for 18 hours. Hides, wool, and mohair are sterilized commercially by gamma-irradiation, usually from a radioactive cobalt source. Special care must be taken to avoid human contact with infected material and, if such contact does occur, the contaminated skin must be thoroughly disinfected. The source of the infection must be traced and steps taken to prevent further spread of the disease. Control of the disease in a feral animal population presents major problems.

Immunization

Immunization of animals as a control measure is extensively used and many types of vaccine are available. Those vaccines that consist of living attenuated strains of the organism with low virulence but capable of forming spores have been most successful. The sporulation character of the vaccine will determine whether the vaccine will be used. Vaccines that consist of living attenuated bacteria have the disadvantage that the organism used in the vaccine may result in some cases from vaccine failures. Vaccines that are killed by heat, or chemicals, have the advantage of keeping the living bacteria alive and, in case the organisms in the vaccine should multiply, the injected animal is likely to be protected. Vaccines that consist of living attenuated bacteria have the disadvantage that the organism used in the vaccine may result in some cases from vaccine failures. Vaccines that are killed by heat, or chemicals, have the advantage of keeping the living bacteria alive and, in case the organisms in the vaccine should multiply, the injected animal is likely to be protected.

The Stern avirulent spore vaccine has the advantage of keeping the living bacteria alive and, in case the organisms in the vaccine should multiply, the injected animal is likely to be protected. Vaccines that are killed by heat, or chemicals, have the advantage of keeping the living bacteria alive and, in case the organisms in the vaccine should multiply, the injected animal is likely to be protected. Vaccines that are killed by heat, or chemicals, have the advantage of keeping the living bacteria alive and, in case the organisms in the vaccine should multiply, the injected animal is likely to be protected. Vaccines that are killed by heat, or chemicals, have the advantage of keeping the living bacteria alive and, in case the organisms in the vaccine should multiply, the injected animal is likely to be protected.

Deaths due to anthrax have occurred in 3-month-old lambs after vaccination with a Stern vaccine and may occur in goats. Older cubs and adults were unaffected. It was assumed that the dose of vaccine was excessive for such young animals. In these species two vaccinations 1 month apart with the first dose one-quarter of the standard dose can be used.5

Diseases associated with Clostridium species

The clostridia are of major importance in farm animals as primary causes of disease. They rarely act as secondary invaders except where gangrene is already present. They are all potent producers of exotoxins, upon which their pathogenicity depends. The toxins of the different organisms vary in their effects and in the manner in which they gain entry to the circulation; they may be:

- Ingested preformed in the feed, as in botulism
- Absorbed from the gut after abnormal proliferation of the causative organism in the alimentary tract, as in enterotoxemia
- Elaborated in a more proper infection of the tissues, such as blackleg

Other clostridial infections develop as local infections with elaboration of toxins in minor lesions, as in tetanus, black disease, braxy and bacillary hemoglobinuria.

Pathogenic clostridia are commonly present in soils rich in humus and may multiply in soil in warm weather following heavy rain. They are also found in the intestinal contents of normal animals and cause disease only in special circumstances. The ubiquitous character of these organisms makes eradication of the clostridial diseases virtually impossible and necessitates control by prophylactic measures. Fortunately, diseases of this group are virtually unique among bacterial infections in that they can be effectively prevented in almost all instances by vaccination with killed culture vaccines.

Because of the common occurrence of a number of clostridial infections in an area, it has become a common practice in recent years to use multivalent bacterin-toxoids containing Clostridium chauvoei, Clostridium septicum, Clostridium novyi, Clostridium sordellii, and Clostridium perfringens types C and D. The vaccines appear to be highly effective and, in situations where the extra expense can be justified, worthy of recommendation. In high-risk situations such as feedlots they appear to be cost-effective. In the USA more than 60% of producers vaccinate calves before weaning for some form of clostridial disease, as do 91% of the larger feedlots.

Prepartum vaccination of the dam, to provide colostral immunity to the young calf or lamb, and subsequent active immunization of the growing animal is recommended for most of the clostridial vaccines. However, because of management constraints, particularly in range beef cattle, clostridial vaccines are not always administered at the age and time recommended by the manufacturers. This may result in suboptimal protection. Clostridial vaccines are usually given to nursing beef calves at the time when they are first handled for castration and branding, at 1–4 months of age. With most clostridial vaccines a booster vaccination is recommended 2–6 weeks following the primary vaccination, but this may not be given until weaning in range cattle.

Clostridial vaccines administered intramuscularly can cause injection site lesions and severe damage to muscle that can persist for 7–12 months after vaccination; in the USA approximately 10% of top sirloin cuts have lesions at slaughter. These must be trimmed from the carcass at slaughter and, if not detected at that time can result in unfavorable experiences by beef consumers and a loss in confidence in the quality of beef products. Multivalent vaccines cause more damage and there is variation in the degree of damage with different vaccines. The prevention of injection site lesions in muscle is a focus of beef quality assurance programs in several countries, and subcutaneous administration of vaccines in the neck area is recommended. Subcutaneous administration will result in subcutaneous injection site lesions and the dichotomy is that cattle that develop injection site lesions have a better antibody response to the vaccine than nonlesioned cattle.

There appears to be a difference between sheep and goats with respect to their response to clostridial infections. Goats in general suffer more severe forms of these diseases than do sheep, and the protection afforded to goats by multivalent vaccines is less than that afforded to sheep.

As well as the specific disease entities set out below there are some less well-known occurrences of pathogenic clostridia.

Clostridium sordellii abomasitis
C. sordellii appears to be an emerging pathogen for sheep in Great Britain and possibly Europe in association with a syndrome of abomasitis and sudden death in young lambs and adult sheep. Death is reported in 6 hours in sheep previously observed to be normal. Lambs between 3 and 10 weeks of age are particularly at risk and losses vary from sporadic to up to 8%.

Commonly the lambs are from well-managed flocks and from good milking ewes. Many of the affected lambs have had ad libitum access to creep pellets from an early age, and this may be a risk factor. The characteristic finding at necropsy is a severe abomasitis with areas of congestion and erosion on the abomasal folds, gastrorrhagia and subserosal emphysema and edema. Sudden death with abomasitis also occurs in weaned and adult sheep but subserosal emphysema and edema are not present. C. sordellii is also recorded as a cause of sudden death in periparturient sheep. Carcasses show...
rapid decomposition but the salient finding is metritis with a uterine wall that is greatly thickened and emphysematous.

*Clostridium sordellii* has also been associated with fatal hepatitis in newborn lambs, enteritis with hemorrhagic diarrhea in calves and in mature cattle can be an agent in blackleg or malignant edema.

**Sudden death syndrome**

Clostridial infection has been considered a cause of a sudden death syndrome in feedlot cattle, which occurs following the acclimatization phase of feeding and presents as death without premonitory signs of illness or agonal struggling and with rapid autolysis of the carcass and no evidence, on postmortem examination, of the common diseases that cause rapid death in feedlot cattle. However, a large controlled trial found no effect on mortality rates from sudden death syndrome from booster vaccination of feedlot cattle with a multivalent bacterin-toxoid (*C. chauvoei*, *C. septicum*, *C. novyi*, *C. sordellii*, and *C. perfringens* types C and D).10

**Enteritis associated with clostridia**

The enteric diseases associated with *C. perfringens* and *Clostridium difficile* are described under those headings. *Clostridium tertium* has been isolated from the intestine of cattle with diarrhea and a mild enteritis has been reproduced by experimental challenge with this organism.11 *C. sordellii* and *Clostridium cadaveris* have been isolated from cases of enterocolitis in horses.

**REFERENCES**

**TETANUS**

**ETIOLOGY**

An exotoxin, tetanospsamin, is produced by *Clostridium tetani* growing under anaerobic conditions. The organism forms spores that can persist in soil for many years. The spores are resistant to many standard disinfection procedures, including steam heat at 100°C (212°F) for 20 minutes but can be destroyed by heating at 115°C (239°F) for 20 minutes.

**Epidemiology**

All species susceptible. Usually a history of a wound or other tissue trauma. Occurs as isolated cases but also as outbreaks in young ruminants following castration and docking.

**Clinical findings**

Generalized muscular rigidity and spasms, hyperesthesia, prolapse of third eyelid, trismus, convulsions, respiratory arrest, and death. High case fatality.

**Necropsy findings**

None. May demonstrate the organism in necrotic tissue in some cases.

**Diagnostic confirmation**

No definitive antemortem test or postmortem lesion. Diagnosis is based on characteristic clinical signs and wound history.

**Treatment**

Neutralize residual toxin, control muscle spasms until the toxin is eliminated or destroyed, maintain hydration and nutrition, provide supportive treatment.

**Control**

Antitoxin if recent injury but risk of serum hepatitis in horses.

**EPIDEMIOLOGY**

**Occurrence**

Tetanus occurs in all parts of the world and is most common in closely settled areas under intensive cultivation. It occurs in all farm animals, mainly as individual, sporadic cases, although outbreaks are occasionally observed in young cattle, young pigs, and lambs following wounding management procedures.

**Case fatality rate**

In young ruminants the case fatality rate is over 80%, but the recovery rate is high in adult cattle. In horses it varies widely between areas. In some areas almost all animals die acutely, in others the mortality rate is consistently about 50%.

**Source of infection**

*C. tetani* organisms are commonly present in the feces of animals, especially horses, and in the soil contaminated by these feces. Surveys in different areas of the world show it is present in 30–42% of soil samples.1 The survival period of the organism in soil varies very widely from soil to soil.

**Transmission**

The portal of entry is usually through deep puncture wounds but the spores may lie dormant in the tissues for some time and produce clinical illness only when tissue conditions favor their proliferation. For this reason the portal of entry is often difficult to determine. Puncture wounds of the hooves are common sites of entry in horses. Introduction to the genital tract at the time of parturition is the usual portal of entry in cattle. A high incidence of tetanus may occur in young pigs following castration and in lambs following castration, shearing, docking, vaccinations, or injections of pharmaceuticals, especially anthelmintics. Docking by the use of elastic band ligatures is reputed to be especially hazardous. *Neonatal tetanus* occurs when there is infection in the umbilical cord associated with insanitary conditions at parturition.

Outbreaks of ‘idiopathic tetanus’ occur occasionally in young cattle without a wound being apparent, usually in association with the grazing of rough, fibrous feed, and it is probable that toxin is produced in wounds in the mouth or gastrointestinal tract or is ingested preformed in the feed. Proliferation in the rumen may also result in toxin production.

**Animal risk factors**

The neurotoxin of *C. tetani* is exceedingly potent but there is considerable variation in susceptibility between animal species, horses being the most susceptible and cattle the least. The variation in prevalence of the disease in the different species is partly due to this variation in susceptibility but is also because exposure and wounding management practices are more likely to occur in some species than in others.

**Importance**

Tetanus is important because of its high case fatality and the very long convalescence in the survivors.

**PATHOGENESIS**

The tetanus bacilli remain localized at their site of introduction and do not invade surrounding tissues. They proliferate and produce tetanoslysin and tetanospsamin only if certain environmental conditions are attained, particularly a lowering of the local tissue oxygen tension. Tetanoslysin promotes local tissue necrosis. Toxin production may occur immediately after introduction if the accompanying trauma has been sufficiently severe, or if foreign material has also been introduced to the wound, or may be delayed for several months until subsequent trauma to the site causes tissue damage. The original injury may be inapparent by then.

Tetanospsamin diffuses to the systemic circulation, is bound to motor end-plates and travels up peripheral nerve trunks via retrograde intra-axonal transport. The exact mechanisms by which the toxin exerts its effects on nervous tissue are not known2 but it blocks the spontaneous and nerve-impulse-evoked release of neurotransmitter, resulting in the disinhibition of gamma motor neurones. No structural lesions are produced but there is central potentiation of normal sensory stimuli so
Diseases associated with *Clostridium* species

**DIFFERENTIAL DIAGNOSIS**

Fully developed tetanus is so distinctive clinically that it is seldom confused with other diseases. The muscular spasms, the prolap of the third eyelid and a recent history of accidental injury or surgery are characteristic findings. However, in its early stages, tetanus may be confused with other diseases.

**All species**
- Strachne poisoning
- Meningitis
- Acute laminitis
- Hyperkalemic periodic paralysis
- Myositis, particularly after injection in the cervical region

**Ruminants**
- Hypomagnesemia – cows, sheep and calves
- White muscle disease
- Polioencephalomalacia
- Enteroxemia

---

**that a state of constant muscular spasticity is produced and normally innocuous stimuli cause exaggerated responses. Death occurs by asphyxiation due to fixation of the muscles of respiration.**

**CLINICAL FINDINGS**

The incubation period varies between 3 days and 4 weeks, with occasional cases occurring as long as several months after the infection is introduced. In sheep and lambs cases appear 3–10 days after shearing or docking.

Clinical findings are similar in all animal species. Initially, there is an increase in muscle stiffness, accompanied by muscle tremor. There is trismus with restriction of jaw movements, prolapse of the third eyelid, stiffness of the hind limbs causing an unsteady, straddling gait, and the tail is held out stiffly, especially when backing or turning. Retraction of the eye and prolapse of the third eyelid – a rapid movement of the third eyelid across the cornea followed by a slow retraction – is one of the earliest and consistent signs (with the exception of sheep) and can be exaggerated by sharp lifting of the muzzle or tapping the face below the eye. Additional signs include an anxious and alert expression contributed to by an erect carriage of the ears, retraction of the eyelids and dilation of the nostrils, and hyperesthesia with exaggerated responses to normal stimuli.

The animal may continue to eat and drink in the early stages but mastication is soon prevented by tetany of the masseter muscles, and saliva may drool from the mouth. If food or water are taken, attempts at swallowing are followed by regurgitation from the nose. Constipation is usual and the urine is retained, partly as a result of inability to assume the normal position for urination. The rectal temperature and pulse rate are within the normal range in the early stages but may rise later when muscular tone and activity are further increased. In cattle, particularly young animals, bloat is an early sign but is not usually severe and is accompanied by strong, frequent rumen contractions. As the disease progresses, muscular tetany increases and the animal adopts a 'sawhorse' posture. Uneven muscular contractions may cause the development of a curve in the spine and deviation of the tail to one side. There is great difficulty in walking and the animal is inclined to fall, especially when startled. Falling occurs with the limbs still in a state of tetany and the animal can cause itself severe injury. Once down it is almost impossible to get a large animal to its feet again. Tetanic convulsions begin in which the tetany is still further exaggerated. Opisthotonos is marked, the hind limbs are stuck out stiffly behind and the forelegs forward. Sweating may be profuse and the temperature rises, often to 42°C (107°F). The convulsions are at first only stimulated by sound or touch but soon occur spontaneously. In fatal cases there is often a transient period of improvement for several hours before a final, severe tetanic spasm during which respiration is arrested.

The course of the disease and the prognosis vary both between and within species. The duration of a fatal illness in horses and cattle is usually 5–10 days but sheep usually die on about the third or fourth day. A long incubation period is usually associated with a mild syndrome, a long course and a favorable prognosis. Mild cases that recover usually do so slowly, the stiffness disappearing gradually over a period of weeks or even months. The prognosis is poor when signs rapidly progress. Animals vaccinated in the past year have a better prognosis, as do horses that have received parenteral penicillin and tetanus antitoxin and in which the wound was aggressively cleaned when fresh.3

**CLINICAL PATHOLOGY**

There are no specific abnormalities in blood or cerebrospinal fluid and no antemortem test of value in confirming the diagnosis. Blood levels of tetanus toxin are usually too low to be detected.

**NECROPSY FINDINGS**

There are no gross or histological findings by which a diagnosis can be confirmed, although a search should be made for the site of infection. Culture of the organism is difficult but should be attempted. If minimal autolysis has occurred by the time of necropsy, the identification of large Gram-positive rods with terminal spores ('tennis-racket morphology') in smears prepared from the wound site or spleen is supportive of a diagnosis of tetanus.

**Samples for confirmation of diagnosis**
- Bacteriology – air-dried impression smears from spleen, wound site (cyto – Gram stain), culture swabs from wound site in anaerobic transport media; spleen in sterile, leakproof container (anaerobic CULT, bioassay).

**TREATMENT**

The main principles in the treatment of tetanus are to:
- Eliminate the causative bacteria
- Neutralize residual toxin
- Control muscle spasms until the toxin is eliminated or destroyed
- Maintain hydration and nutrition
- Provide supportive treatment.

There are no structural changes in the nervous system, and the management of cases of tetanus depends largely on keeping the animal alive through the critical stages.

Elimination of the organism is usually attempted by the parenteral administration of penicillin in large doses, preferably by intravenous administration. If the infection site is found, the wound should be aggressively cleaned and debrided but only after antitoxin has been administered, because debridement, irrigation with hydrogen peroxide, and the local application of penicillin may facilitate the absorption of the toxin.

Tetanus antitoxin is administered but is of little value once signs have appeared. After the experimental administration of toxin, antitoxin is of limited value at 10 hours and ineffective by 48 hours. The recommended dose is controversial but for optimal results horses should receive 300,000 IU 12-hourly for three injections. Local injection of some of the antitoxin around the wound is advised. There have been a number of attempts to justify the treatment of early cases of equine tetanus by the intrathecal injection of antitoxin but there is limited evidence of therapeutic value and the procedure carries risk.3,4

Relaxation of the muscle tetany can be attempted with various drugs. Chlorpromazine (0.4–0.8 mg/kg body weight (BW) intravenously, 1.0 mg/kg BW intramuscularly, three or four times daily) and acetyl promazine (0.05 mg/kg BW twice daily) administered until severe signs subside, are widely used.3 A combination of diazepam (0.01–0.4 mg/kg) and xylazine (0.5–1.0 mg/kg, intravenously or intramuscularly) may be effective in horses refractory to phenothiazine tranquilizers.3
Hydration can be maintained by intravenous or stomach-tube feeding during the critical stages when the animal cannot eat or drink. The use of an indwelling tube should be considered because of the disturbance caused each time the stomach tube is passed. Feed and water containers should be elevated and the feed should be soft and moist.

Additional supportive treatment includes slinging of horses during the recovery period when hyperesthesia is diminishing. Affected animals should be kept as quiet as possible and provided with dark, well-bedded quarters with nonslip flooring and plenty of room to avoid injury if convulsions occur. Administration of enemas and catheterization may relieve the animal's discomfort. This level of nursing, plus penicillin, ataractic, and analgesics may relieve the animal's discomfort. This level of nursing, plus penicillin, ataractic, and analgesics may relieve the animal's discomfort. This level of nursing, plus penicillin, ataractic, and analgesics may relieve the animal's discomfort. This level of nursing, plus penicillin, ataractic, and analgesics may relieve the animal's discomfort.

Horses that fall frequently sustain bone fractures and may need to be destroyed.

CONTROL

Many cases of tetanus could be avoided by proper skin and instrument disinfection at castrating, docking, and shearing time. These operations should be carried out in clean surroundings; in the case of lambs cleaned aggressively. Tetanus toxoid can be administered at the same time as tetanus antitoxin, provided they are injected at different sites and using different syringes. Animals that suffer injury are usually given an injection of antitoxin and one of toxoid to insure complete protection.

Tetanus antitoxin should be given to any animal with a penetrating wound or deep laceration, and the wound should also be aggressively treated. Tetanus toxoid can be administered at the same time as tetanus antitoxin, provided they are injected at different sites and using different syringes. Animals that suffer injury are usually given an injection of antitoxin and one of toxoid to insure complete protection.

Tetanus antitoxin is often routinely given to mares following foaling and to newborn foals. In some areas the risk for tetanus in young foals is high, antitoxin is usually given at the time of docking or castration; 200 IU has been shown to be effective. The risk for tetanus in calves is lower than in lambs and tetanus antitoxin is not commonly given at the time of castration.

There is a risk for serum hepatitis in horses that have been given tetanus antitoxin and, while this risk is small, a policy of routine active immunization of the mare to provide the mare with active immunity and the foal with passive immunity is preferred to one that relies on antitoxin. Provided foals get an adequate supply of colostrum they are protected during the first 10 weeks of life by active vaccination of the mare during the last weeks of pregnancy. Prevention of tetanus in newborn lambs is also best effected by vaccination of the ewe in late pregnancy.

Active immunity

Available vaccines are formalin-inactivated adjuvanated toxoids; they induce long-lasting immunity. Primary vaccination requires two doses 3–6 weeks apart. Protective titers are obtained within 14 days of the second injection and last for at least a year and up to 5 years. Traditionally foals have received primary vaccination at 3–4 months of age, however there is evidence that maternal antibodies acquired by foals born to mares vaccinated shortly before parturition significantly inhibit the antibody response of the foal to primary vaccination until it is 6 months of age and that primary vaccination should be delayed until that age.

Although immunity lasts longer than 1 year, it is common to revaccinate horses yearly with a single booster injection. Pregnant mares should receive a booster injection 4–6 weeks before foaling to provide adequate colostral immunity to the foal.

Ewes are immunized with a similar schedule except that the primary doses are usually given at a managementally convenient time when the flock is yared. A prelaming booster vaccination is given yearly. Commonly, commercial vaccines for sheep also contain antigens for other clostridial diseases for which sheep are at high risk.

Vaccination of cattle is usually not considered unless an outbreak of the disease has occurred in the immediate past and further cases may be anticipated.

REFERENCES

ETIOLOGY

The causative organism Clostridium botulinum, a spore-forming anaerobe, produces neurotoxins during vegetative growth. Spores can survive in the environment for over 30 years. Under favorable conditions of warmth and moisture, the spores germinate and vegetative cells multiply rapidly, elaborating a stable and highly lethal toxin which, when ingested, can cause disease. The toxin is also capable of surviving for long periods, particularly in bones or if protected from leaching. Seventeen genetically distinct toxin types (A–G), some with subtypes, have been identified.

Some farm animal diseases are produced primarily by types B, C, and D. The geographical distribution of these types varies considerably. In a study in the USA, type A was found in neutral or alkaline soils in the west, while types B and E were in damp or wet soils in the east. Type C was found in acid soils in the Gulf coast, and type D in alkaline soils in the west. Microorganisms capable of inhibiting C. botulinum were present, with or without the clostridia, in many soils. Type B is also common in soils in the US and in Europe. Types C and D are more common in warmer climates.

The organism is present in the alimentary tract of animals that have recently eaten

BOTULISM

ETIOLOGY

Neurotoxin produced by Clostridium botulinum during vegetative growth. C. botulinum types B, C, and D are associated with disease in animals but the type prevalence varies geographically.

Epidemiology

Ingestion of preformed toxin where feed preparation or storage allows multiplication of the organism in the feed with toxin production.

Contamination of feed with carrion containing toxin. Consumption of carrion on pasture by phosphorus-deficient animals. Risk factors often result in multiple cases. Rare cases occur from toxin production from organisms in the intestine of wounds.

Clinical findings

Early muscle tremor, progressive symmetrical weakness, and motor paralysis leading to recumbency. Mydriasis, ptosis, weak tongue retraction; sensation and consciousness retained until death.

Necropsy findings

None specific.

Diagnostic confirmation

Demonstration of toxin in serum or feed. Demonstration of organisms in feed, intestinal contents, or wounds.

Treatment

Type-specific antiserum and supportive treatment.

Control

Avoidance of exposure by feed management. Vaccination.

E. coli B

is often present in the alimentary tract of animals that have recently eaten

B. subtilis

in in vivo conditions that rely on antitoxin. Provided foals get an adequate supply of colostrum they are protected during the first 10 weeks of life by active vaccination of the mare during the last weeks of pregnancy. Prevention of tetanus in newborn lambs is also best effected by vaccination of the ewe in late pregnancy.

Active immunity

Available vaccines are formalin-inactivated adjuvanated toxoids; they induce long-lasting immunity. Primary vaccination requires two doses 3–6 weeks apart. Protective titers are obtained within 14 days of the second injection and last for at least a year and up to 5 years. Traditionally foals have received primary vaccination at 3–4 months of age, however there is evidence that maternal antibodies acquired by foals born to mares vaccinated shortly before parturition significantly inhibit the antibody response of the foal to primary vaccination until it is 6 months of age and that primary vaccination should be delayed until that age.

Although immunity lasts longer than 1 year, it is common to revaccinate horses yearly with a single booster injection. Pregnant mares should receive a booster injection 4–6 weeks before foaling to provide adequate colostral immunity to the foal.

Ewes are immunized with a similar schedule except that the primary doses are usually given at a managementally convenient time when the flock is yared. A prelaming booster vaccination is given yearly. Commonly, commercial vaccines for sheep also contain antigens for other clostridial diseases for which sheep are at high risk.

Vaccination of cattle is usually not considered unless an outbreak of the disease has occurred in the immediate past and further cases may be anticipated.

ingested contaminated material and may be introduced into new areas in this way, or by birds and blowflies.

**Epidemiology**

**Occurrence**

Botulism has no geographical limitations, isolated cases and sporadic outbreaks occurring in most countries. The source of exposure to toxin and the risk for disease differ between regions because of differences in food storage, feeding, and management practices. Outbreaks associated with ingestion of toxin in conserved feeds are more common in the northern states of the USA and in Europe whereas outbreaks in animals on pasture are reported primarily from South Africa, Australia, and the Gulf coast area of the USA. The disease usually occurs in a number of animals at one time and has a high case fatality rate.

**Source of infection**

Most incidents of botulism are associated with the ingestion of preformed toxin (forage botulism). Toxin in feeds may result from the primary growth of *C. botulinum* in the feed or from the contamination of the feed with toxin-containing carrion (carrion-associated botulism). Less common sources are growth with toxin production in wounds (wound botulism) or growth and toxin production in the alimentary tract (toxicoinfectious botulism).

Forage botulism

Forage botulism occurs when pH, moisture, and anaerobic conditions in the feedstuff allow the vegetative growth of *C. botulinum* and the production of toxin. This can occur in a number of spoiled stored forages. Cereal silages carry a risk in the USA. Silage and hay may spoil to a stage suitable for the growth of *C. botulinum*. This is most likely if the forage is very succulent or is wet by rain when it is made.

**Big bale silage** is a particular risk. The type of forage ensiled in big bales often has insufficient water-soluble carbohydrate for adequate lactic acid fermentation to achieve a stable low pH, and the higher dry matter content can also lead to a higher pH. Clotstridial multiplication is inhibited below pH 4.5. Most non-carrion-associated botulism is due to type B strains, and horses appear to be especially susceptible.

Proliferation of the organism can occur in **decaying vegetable material**. The disease has also occurred in horses fed on spoiled vegetables and potatoes contaminated by *C. botulinum*, and on alfalfa haylage packed in airtight aluminum foil envelopes. Grass clippings allowed to accumulate and decay in a pile have poisoned horses, as has round bale hay that spoiled after rain. Decaying grass at the base of old tussocks and in trampled stubble are known to be suitable sites for growth of *C. botulinum*. Cases have occurred with brewer's grains, and high-moisture grain has the potential for toxicity.

Carrion-associated botulism

This is almost always the cause of botulism in animals on pasture, and carrion is also a common cause of botulism in animals on conserved feeds. Carrion includes domestic and wild animals and birds. In endemic botulism areas, the carcass of dead animals is invaded by *C. botulinum* and high concentrations of toxin are produced such that very small amounts of flesh or bone have lethal concentrations. Most outbreaks of carrion-associated botulism are associated with type C and D strains, these strains producing much higher concentrations of toxin in carrion than type A and B strains.

Toxin can persist in carrion for at least 1 year. Where the carcasses of rodents, cats, and birds contaminate hay or silage, toxin can leach out and contaminate surrounding hay or other feeds to cause multiple cases of botulism. In one instance a single mouse carcass is believed to have contaminated 200 000 tons of alfalfa cubes. A common source in Australia is hay made at the time of a mouse plague. At such times even good, fresh hay can contain a great deal of carrion. In another recorded incident 427 of 444 dairy cattle died after ingesting feed contaminated with *botulinum* type C toxin from a cat carcass.

**Poultry manure and ensiled poultry litter** have caused outbreaks of botulism when used as cattle feed, as has poultry litter used for bedding cattle. Outbreaks of botulism have occurred in cattle and sheep grazing pastures that have been fertilized with poultry manure or poultry litter. Cattle and sheep may eat poultry litter piled on a pasture prior to disposal. It is probable that the source of toxin in poultry litter is from poultry carcasses. Disease is usually due to *C. botulinum* type C.

**Direct carrion ingestion** can occur where cattle subsist on a phosphorus-deficient diet and manifest osteopathia, with subsequent ingestion of carrion. The disease is likely to occur in outbreak form. In *sheep*, pica is more usually associated with a dietary deficiency of protein or net energy. Occasional outbreaks occur that are due to drinking of water contaminated by carcasses of dead animals. A not uncommon occurrence is in livestock drinking lake water contaminated by the carcasses of ducks and other waterfowl that have died of botulism. Wetlands where outbreaks of avian botulism have occurred are likely to have repeated occurrences because of soil contamination.

**Wound botulism**

Wound botulism is rare but is recorded in horses following castration, with omphalophlebitis, umbilical hernias treated with clamps, with an infected wound and in association with an injection abscess.

**Toxicoinfectious botulism**

This results when toxin is produced by *C. botulinum* present in the intestine. The disease is also called the *shaker foal syndrome*. It is a disease of young foals up to 8 months of age with the highest prevalence in foals 3–8 weeks of age.

The disease occurs sporadically in the USA, Australia, and the UK but may occur repeatedly on some farms. *C. botulinum* type B has been isolated from the feces of naturally occurring cases of the disease and the condition has been produced experimentally by the intravenous injection of *C. botulinum* toxin.

**Toxicoinfectious botulism** is also postulated as the possible cause of equine grass sickness (equine dystautonomia) which is described elsewhere in this text.

**Experimental reproduction**

Cows challenged with type C *botulinum* toxin intravenously showed initial signs of constipation and straining at defecation 48 hours after injection and weakness, decreased tail tone, decreased tongue tone and muscle fasciculation of large-muscle groups between 76 and 92 hours. Weakness progressed to total posterior paresis between 80 and 140 hours in these cattle. On a weight-for-weight basis, cattle were considered to be 13 times more sensitive than mice to type C *botulinum* toxin.

**Risk factors**

**Animal risk factors**

Botulism is most common in birds, particularly the domestic chicken and wild waterfowl. Cattle, sheep, and horses are susceptible but pigs, dogs, and cats appear to be resistant. The horse appears to be particularly susceptible to type B toxin. Cattle and sheep are usually affected by types C and D.

**Environment risk factors**

Botulism in range animals has a seasonal distribution. Outbreaks are most likely to occur during drought periods when feed is sparse, phosphorus intake is low and carrion is plentiful. Silage-associated botulism is also seasonal with the feeding of silage. The variation that occurs in the geographical distribution of the various types, and in carrion versus non-carrion-associated botulism is an important factor when considering prophylactic vaccination programs.
**Importance**

Severe outbreaks with high case fatality rates can occur when contaminated feed is fed to large numbers of animals. Under extensive grazing conditions massive outbreaks of carrion-associated botulism also occur unless the animals are vaccinated.

**Zoonotic implications**

Botulinum toxin is identified as a possible agent for bioterrorism. The meat and milk from cattle that have botulism should not be used for human consumption.

**PATHOGENESIS**

The toxins of *C. botulinum* are neurotoxins and produce functional paralysis without the development of histological lesions. Botulinum toxins are absorbed from the intestinal tract or the wound and carried via the bloodstream to peripheral cholinergic nerve terminals including neuromuscular junctions, postganglionic parasympathetic nerve endings, and peripheral ganglia. The heavy chain of the toxin is responsible for binding to the receptors and translocation into the cell and the light chain of the toxin for resultant blockade of the release of acetylcholine at the neuromuscular junction. Flaccid paralysis develops and the animal dies of respiratory paralysis.

**CLINICAL FINDINGS**

**Cattle and horses**

Signs usually appear 3–17 days after the animals gain access to the toxic material, but occasionally as soon as 1 day. The incubation period being shorter as the amount of toxin available is increased.

**Peracute cases** die without prior signs of illness, although a few fail to take water or food for a day beforehand. The disease is not accompanied by fever and the characteristic clinical picture is one of progressive symmetric muscular paralysis affecting particularly the limb muscles and the muscles of the jaw, tongue, and throat. Muscle weakness and paralysis commence in the hindquarters and progress to the forequarters, head, and neck. The onset is marked by very obvious muscle tremor and fasciculation, often sufficient to make the whole limb tremble. Colic may be an initial sign in horses.

In most cases the disease is **subacute**. Restlessness, incoordination, stumbling, knuckling, and ataxia are followed by inability to rise or to lift the head. Mydriasis and ptosis occur early in the clinical course; mydriasis can be prominent in type C botulism in the horse. Skin sensation is retained. Affected animals lie in sternal recumbency with the head on the ground or turned into the flanks, not unlike the posture of a cow with parturient paresis.

Muscle weakness and paralysis commence at the neuromuscular junction. Flaccid paralysis develops and the animal dies of respiratory paralysis.

**Sheep**

Sheep do not show the typical flaccid paralysis of other species until the final stages of the disease. There is stiffness while walking, and incoordination and some excitability in the early stages. The head may be held on one side or bobbed up and down while walking (limber neck). Lateral switching of the tail, salivation, and serous nasal discharge are also common. In the terminal stages there is abdominal respiration, limb paralysis, and rapid death.

**Pigs**

Authentic reports in this species are rare. Clinical signs include staggering followed by recumbency, vomition, and papillary dilatation. The muscular paralysis is flaccid and affected animals do not eat or drink.

**CLINICAL PATHOLOGY**

There are no changes in hematological values or serum biochemistry that are specific to botulism.

Hypophosphatemia may be present where this is a risk factor. Muscle enzyme activities may be moderately elevated.

In foals, arterial blood analysis shows acidemia, hypercapnia, hypoxemia, and desaturation of hemoglobin, and repeated arterial blood gas analyses should be conducted during the first 48 hours of treatment as a significant proportion of foals will require some form of ventilatory support.

Laboratory diagnosis of botulism in the live or dead animal is difficult because of the lack of sensitive confirmatory laboratory tests. Laboratory confirmation is attempted by:

- Detection of preformed toxin (or toxin itself) in serum, intestinal tract contents, or feed
- Demonstration of spores of *C. botulinum* in the feed or gastrointestinal contents
- Detection of antibody in recovering or clinically normal at-risk animals.

**Detection of toxin** using bioassay in mice coupled with toxin neutralization with polyvalent antitoxin is used but the sensitivity is low in both ruminants and horses as they are substantially more sensitive than mice to botulinum toxin.

In outbreaks of botulism it is not uncommon to have only a proportion of clinically affected animals, or none, test positive. Protection with monovalent antitoxin allows type identification. Toxin detection by an enzyme-linked immunosorbent assay (ELISA) test appears less sensitive than mouse bioassay. The specificity is lower and the sensitivity is lower in ruminants compared to other species.
sensitive than mouse bioassay.\textsuperscript{21} Toxin production or carrion contamination can potentially occur in a number of feeds; however the majority of outbreaks are associated with contamination in hay or silage\textsuperscript{3} and suspect feeds should be tested in mice for toxin. To get around the problem of lack of sensitivity with the mouse test, suspect feed has been fed to experimental cattle. Alternatively one can make an infusion of the feed sample and use as the sole drinking water supply for experimental animals. The problem with all feeding experiments is that the botulinum toxin is likely to be very patchy in its distribution in the feed.

Failure to produce the disease in animals vaccinated against botulism, when deaths are occurring in the unvaccinated controls, has also been used as a diagnostic procedure.

**Demonstration of spores of** C.\textit{botulinum} **in the feed being fed or the feaces of affected animals supports a diagnosis of botulism as botulism spores are rarely detected in the feaces of normal foals and adult horses.\textsuperscript{5}**

The detection of antibody in chronically affected animals and at-risk herd mates by an ELISA test has been used to support a diagnosis in outbreaks of type C and type D botulism.\textsuperscript{22,23} It has been used in range cattle where acutely affected clinical cases or fresh animals for postmortem toxin testing were not available. Cattle exposed to sublethal and subclinical amounts of toxin with sufficient immunogenicity develop a specific antibody response.\textsuperscript{23} An increased antibody prevalence over time or an increased antibody prevalence in an affected group compared with a similar group nearby suggests exposure to the toxin.

### NECROPSY FINDINGS

There are no specific changes detectable at necropsy, although the presence of suspicious feedstuffs in the forestomachs or stomach may be suggestive. There may be nonspecific subendocardial and subepicardial hemorrhages and congestion of the intestines. Microscopic changes in the brain are also nonspecific, consisting mainly of perivascular hemorrhages in the corpus striatum, cerebellum, and cerebrum. Nonetheless, unless classic flaccid paralysis was observed clinically, the brain should be examined histologically to eliminate other causes of neurological disease. The presence of C.\textit{botulinum} in the alimentary tract is a further test. The presence of toxin in the gut contents is confirmatory if found but is often misleading, because the toxin may have already been absorbed. The presence of the toxin in the liver at postmortem examination is taken as evidence that the disease has occurred. In addition to traditional bioassays such as the mouse protection test, newer methods for toxin detection include ELISA techniques, and a recently described immuno-polymerase chain reaction (PCR) assay.\textsuperscript{24}

### Samples for confirmation of diagnosis

- **Bacteriology** – suspected contaminated feed material, liver, rumen contents, plus serum from clinically affected herdmates (bioassay, anaerobic CULT, ELISA)
- **Histology** – formalin-fixed brain.

### DIFFERENTIAL DIAGNOSIS

A presumptive diagnosis is made on the clinical signs and history, occurrence in unvaccinated animals and the ruling out of other diseases with a similar clinical presentation. The symmetric motor paralysis of botulism with muscle paralysis that progresses to recumbency in 1–4 days is a major differential for botulism from other causes of neurological dysfunction in large animals.

**Ruminants**

Clinically and at necropsy the disease resembles parturient paresis in cattle and hypocalcemia in sheep but the conditions under which the diseases occur are quite different.

- Tick paralysis
- Paralytic rhabdomyolysis
- Poisoning by \textit{Phalaris aquatica}
- Organophosphate carbamate poisoning
- Louping ill in sheep

**Horses**

- Equine protozoal myelitis
- Equine encephalomyelitis
- Hepatic encephalopathy
- Paralytic rhabdomyolysis
- Ionophore toxicity

### TREATMENT

Recent studies report a survival rate in foals of 96% which was achieved by the early administration of antitoxin (before complete recumbency) coupled with a high quality of intensive care fluid therapy, enteral or parenteral feeding, nasal insufflation with oxygen and mechanical ventilation if required. Duration of hospitalization approximated 2 weeks.\textsuperscript{11} Antitoxin was considered essential to the treatment and enteral feeding. Extravascular or intravenous feeding is usually necessary and may not prevent the occurrence of botulism in foals.\textsuperscript{11}

**Animals should be confined to a stall with supportive fluid therapy and enteral feeding.** Muzzling may be required to prevent aspiration pneumonia and frequent turning to prevent muscle necrosis and decubital ulcers. Bladder catheterization may be required in horses that do not urinate and mechanical ventilation may be necessary for recumbent horses.

Mineral oil is used to prevent constipation and enteral or parenteral feeding, nasal insufflation with oxygen and mechanical ventilation may be necessary for recumbent horses.

### CONTROL

In range animals, **correction of dietary deficiencies** by supplementation with phosphorus or protein should be implemented if conditions permit. Hygienic disposal of carcasses is advisable to prevent further pasture contamination but may not be practicable under range conditions. **Vaccination** with type-specific or combined (bivalent C and D) toxoid is practiced in enzootic areas in Australia and southern Africa. Type B and C vaccines would be more appropriate for prevention of disease in North America and Europe.

The immunity engendered by vaccination is type-specific. The number and interval of vaccinations required varies with the vaccine, and the manufacturer's directions should be followed. In horses, the disease is usually sporadic and due to accidental contamination of feed or water; vaccination is seldom practiced in this species. Some local reactions are encountered after vaccination in horses but they are seldom serious. Vaccination of the mare may not prevent the occurrence of botulism in foals.\textsuperscript{11}

A common problem that arises when the disease appears to have resulted from feeding contaminated silage, hay, or other feed is what to do with the residue of the feed; there may be a large quantity of it. In these circumstances the stock should be vigorously vaccinated with a toxoid on three occasions at 2-week intervals and then feeding of the same material can be recommenced.
Blackleg is a disease in cattle that is caused by the bacterium *Clostridium chauvoei*. It is common in cattle under two years of age and is usually acquired through direct contact with infected animals. The disease can also be transmitted by the ingestion of contaminated feed or through bites from other infected animals.

**Etiology and Pathogenesis**

The disease is characterized by the development of clostridial myositis, a condition where the bacteria infect the muscles of the body, particularly the muscles of the neck, shoulder, and hind legs. The bacteria are resistant to many antibiotics and can survive for long periods in the environment.

**Transmission**

The disease is primarily transmitted through direct contact with infected animals, but it can also be transmitted through contaminated feed or water. The bacteria can survive in the environment for several days, making it difficult to control.

**Risk Factors**

The risk factors for blackleg include:

- Age: Cattle under two years of age are at highest risk.
- Trauma: Injuries or surgery can increase the risk of blackleg.
- Environmental conditions: The disease is more common in areas with high humidity and temperature.
- Vaccination status: Cattle that are not properly vaccinated are at higher risk.

**Clinical Signs**

The clinical signs of blackleg include:

- High fever
- Difficulty breathing
- Shaking
- Poor feed intake
- Lethargy
- Respiratory distress

**Diagnosis**

Diagnosis of blackleg can be challenging due to the similar clinical signs of other diseases. A culture of the affected tissue or blood can help confirm the diagnosis. Serological tests are also available.

**Treatment**

Treatment for blackleg is supportive and includes:

- Analgesics
- Vitamin supplements
- Supportive care

**Prevention**

Prevention of blackleg involves:

- Proper vaccination
- Good herd management
- Sanitation and hygiene

**Conclusion**

Blackleg is a serious disease that can cause significant economic losses to farmers. Proper management practices and vaccination are key to preventing the spread of this disease.
**CLINICAL FINDINGS**

**Cattle**

If the animal is observed before death there is severe lameness, usually with pronounced swelling of the upper part of the affected leg. On closer examination the animal will be found to be very depressed and have complete anorexia and ruminal stasis, and a high temperature (41°C, 106°F) and pulse rate (100–120/min). Pyrexia is not present in all cases. In the early stages the swelling is hot and painful to the touch but soon becomes cold and painless, and edema and emphysema can be felt. The skin is discolored and soon becomes dry and cracked.

Although the lesions are usually confined to the upper part of one limb, occasional cases are seen where the lesions are present in other locations such as the base of the tongue, the heart muscle, the diaphragm and psoas muscles, the brisket, and theudder. Lesions are sometimes present in more than one of these locations in one animal. The condition develops rapidly and the animal dies quietly 12–36 hours after the appearance of signs. Many animals die without signs having been observed.

**Sheep**

When blackleg occurs in the limb musculature in sheep, there is a stilt gait and the sheep is disinclined to move because of severe lameness in one limb or, more commonly, in several limbs. The lameness may be severe enough to prevent walking in some animals but be only moderate in others. Subcutaneous edema is not common and gaseous crepitation cannot be felt before death. Discoloration of the skin may be evident but skin necrosis and gangrene do not occur.

In those cases where infection occurs through wounds of the skin, vulva, or vagina there is an extensive local lesion. Lesions of the head may be accompanied by severe local swelling due to edema and there may be bleeding from the nose. In all instances there is high fever, anorexia, and depression, and death occurs very quickly. Sheep and cattle with cardiac myositis associated with *C. chauvoei* are usually found dead.3,4

**Horses**

The clinical syndrome in horses is not well defined. Rectal edema, stiff gait, and incoordination are recorded.1

**NECROPSY FINDINGS**

**Cattle**

Cattle found dead of blackleg are often in a characteristic position; lying on the side with the affected hindlimb stuck out stiffly. Boating and putrefaction occur quickly and bloodstained froth exudes from the nostrils and anus. Clopping of the blood occurs rapidly. Incision of the affected muscle mass reveals dark red to black, swollen tissue with a rancid odor and thin, sanguineous fluid containing bubbles of gas. Freshly cut surfaces are often dry and may have a metallic sheen. The heart and all skeletal muscles, including those of the tongue, diaphragm, and lumbar region, must be checked, as the lesion may be small and escape cursory examination. The thoracic cavity and the pericardial sac may contain excess blood-stained fluid with variable amounts of fibrin. This serositis is often overlooked, or is misinterpreted as a component of pleuropneumonia. The lungs are usually congested and may be atelectatic as a result of abdominal tympany.

In sheep the muscle lesions are more localized and deeper and the subcutaneous edema is not so marked, except around the head. Gas is present in the affected muscles but not in such large amounts as in cattle. When the disease has resulted from infection of skin wounds, the lesions are more obvious superficially, with subcutaneous edema and swelling and involvement of the underlying musculature. When invasion of the genital tract occurs, typical lesions are found in the perineal tissues and in the walls of the vagina and occasionally the uterus. In the special case of pregnant ewes, typical lesions may involve the entire fetus and cause abdominal distension in the ewe.

Histologically, blackleg cases feature myonecrosis, edema, emphysema, and an unimpressive neutrophilic cellulitis. Organisms may be few in number but can usually be seen in tissue sections. Smears from the affected tissue should be made and material collected for bacteriological examination. The isolation and identification of *C. chauvoei* and *C. novyi* is difficult because of the fastidiousness of these species in culture and rapid postmortem contamination of the tissues by clostridial species from the gastrointestinal tract. Thus it is essential that tissues be examined as soon after death as possible.2 Most laboratories use fluorescent antibody tests performed on tissue smears to complement (or substitute) anaerobic culture.

False blackleg may be associated with *C. septicum* and *C. novyi* but this disease is more accurately classified as malignant edema. Mixed infections with *C. chauvoei* and *C. septicum* are not uncommon but the significance of *C. septicum* as a cause of the disease is debated. However, in a study of 176 cases of clostridial myositis in cattle, *C. chauvoei* either alone or with *C. septicum* was demonstrated in 56%. In 36%, *C. novyi* was found alone or with *C. septicum*. This indicates that maximum protection to cattle can be provided only by a multivalent vaccine that contains the antigens of *C. chauvoei*, *C. novyi*, and *C. septicum*. A multiplex PCR based on the flagellin gene sequence has been used to identify pathogenic clostridia in clinical specimens.6

**DIFFERENTIAL DIAGNOSIS**

In establishing a diagnosis when a number of animals are found dead in a group not kept under close observation and postmortem decomposition is so advanced that little information can be obtained, one must depend on one's knowledge of local disease incidence, season of the year, age group affected and pasture conditions, and on a close inspection of the environment in which the animals have been maintained. More frequent observation should be established so that sick animals or fresh cadavers will be available for examination.

- **Malignant edema.** In typical cases of blackleg in cattle a definite diagnosis can be made on the clinical signs and the necropsy findings. Definitive identification of *C. chauvoei* is by fluorescent antibody staining. Diagnosis on gross postmortem findings from other causes of clostridial myositis is hazardous and may result in improper recommendations for control.
  - Anthrax
  - Lightning strike
  - Bacillary hemoglobinuria
  - Other causes of sudden unexpected death

**TREATMENT**

Treatment of affected animals with penicillin and surgical debridement of the lesion, including fasciostomy, is indicated if the animal is not moribund. Recovery rates are low because of the extensive nature of the lesions. Large doses (40 000 IU/kg BW) should be administered, commencing with crystalline penicillin intravenously and followed by longer-acting preparations. Blackleg antibiotic therapy is unlikely to be of much value in treatment unless very large doses are given.

**Diseases associated with Clostridium species**

- Bacteriology – muscle, placed in airtight container; four air-dried impression smears of surface of freshly cut lesion (anaerobic CULT, FAT)
- Histology – fixed samples of suspected muscle lesion
CONTROL

Cattle
On farms where the disease is enzootic, annual vaccination of all cattle between 3 and 6 months with two vaccinations given 4 weeks apart followed by an annual booster vaccination is recommended. This should be done just prior to the anticipated danger period, usually spring and summer. Maternal immunity persists for at least 3 months and will interfere with active immunity in calves vaccinated before this age.

In an outbreak all unaffected cattle should be vaccinated immediately and injected with penicillin at a dose of 10,000 IU/kg BW intramuscularly or a combination of penicillin and benzathine penicillin. Movement of the cattle from the affected pasture is advisable. If antibiotics are not given, new cases of blackleg may occur for up to 14 days until immunity develops, and constant surveillance and the early treatment of cases will be necessary.

Sheep
With sheep in areas where the disease is enzootic, the maiden ewes should be vaccinated twice, the last vaccination given about 1 month before lambing and a subsequent yearly booster given at the same time before lambing. This will prevent infection of the ewes at lambing and will also protect lambs against umbilical infection at birth and infection of the tail wound at docking, provided the tail is docked at a young age. If an outbreak commences in a flock of ewes at lambing time, prophylactic injections of penicillin and antiserum to ewes requiring assistance are recommended.

A single vaccination of wethers can also be carried out 2–3 weeks before shearing if infection is anticipated. Because of the common occurrences of the disease in young sheep, vaccination before they go on to pasture and are exposed to infection of skin wounds from fighting is recommended in danger areas. The duration of the immunity in these young vaccinated animals is relatively short and ewes in particular must be revaccinated before they lamb for the first time. Clostridial vaccines have poorer antigenicity in sheep and goats than in cattle.

In both sheep and cattle it is advisable to use a combined vaccine containing at least C. chauvoei, C. septicum, and C. novyi, where these organisms occur in the area and cause clostridial myositis.

There is limited information on which to base the recommendations above as there is limited information on the efficacy of available individual manufacturers’ vaccines. There is variability in the immune response and its duration with different vaccines. Vaccine failure has been associated with an inadequate spectrum of the antigens in the vaccine, and in these circumstances a bacterin prepared from a local strain of C. chauvoei is preferred. Vaccines combined with anthelmintics or with trace elements are used in some areas to minimize the number of injections required when processing sheep.

It is important that carcasses of animals dying of blackleg are destroyed by burning or deep burial to limit soil contamination.

**REVIEW LITERATURE**

REFERENCES

5. Williams BM. Vet Rec 1977; 90:100

**MALIGNANT EDEMA, CLOSTRIDIAL MYONECROSIS (GAS GANGRENE)**

**ETIOLOGY**

Clostridium septicum, C. chauvoei, C. perfringens, C. sordellii, and C. novyi have all been isolated from lesions typical of malignant edema of animals. In some cases there can be mixed infections. The occurrence of malignant edema due to C. chauvoei has been discussed in the section on blackleg.

C. sordellii has been associated chiefly with malignant edema of cattle but it has been found to be a cause of malignant edema and swelled head in sheep. However, swelled head of rams, in which the lesions of malignant edema are restricted to the head, is most commonly associated with C. novyi infection.

In a retrospective study of 37 horses with clostridial myonecrosis, C. perfringens was isolated from 68%, C. septicum from 16% and mixed infections with these two species or infection with other clostridia in the remainder.

**EPIDEMIOLOGY**

All ages and species of animals are affected. The clostridia that cause malignant edema are common inhabitants of the animal environment and intestinal tract, and, although some of the causative species have a restricted distribution, the disease is general in most parts of the world. There is sporadic occurrence of the disease except in areas where a management procedure to a group of animals results in an outbreak.

**Source of infection**

The infection is usually soil-borne, and the resistance of spores of the causative clostridia to environmental influence leads to persistence of the infection for long periods in a local area. A dirty environment that permits contamination of wounds with soil is the common predisposing cause.

**Transmission**

In most cases a wound is the portal of entry. Deep puncture wounds accompanied by severe trauma provide the most favorable conditions for growth of anaerobes, and malignant edema occurs most frequently under such conditions. Infection may occur through surgical or accidental wounds following vaccination, intramuscular injection of drugs, veterinarian, or through the umbilical cord in the newborn.
newborn. It is assumed that infection is introduced through the wound but cases of malignant edema can occur following intramuscular injection of drugs despite careful attention to aseptic technique. Dormant spores of *C. perfringens* and other clostridial species can be found in the normal muscle of horses and it is possible in some cases that these may be activated by anaerobic conditions produced by the injected material.

**Animal and management risk factors**

In horses intramuscular injection of drugs, commonly in association with the treatment of colic, is the common precipitating factor. Certain drugs may have a greater propensity to initiate muscle necrosis and disease but these drugs are also commonly used in the treatment of colic. Periavascular leaking of drugs is also a precipitating cause in horses. In all species there is risk with the intramuscular injection of drugs such as anthelmintics and nutritional supplements, some of which can cause significant tissue damage at the site, particularly if proper asepsis is not practiced.

Outbreaks can occur in sheep after management practices such as shearing, and docking, or following lambing. Outbreaks have also been observed in cattle following parturition, sometimes associated with lacerations of the vulva. An unusual method of infection occurs when crows that have eaten infected carrion carry the infection to live, weak sheep and to lambs when they attack their eyes. Castration wounds in pigs and cattle may also become infected. Unless treatment is instituted in the early stages the death rate is extremely high.

The practice of dipping sheep immediately they are shorn may cause a high incidence of malignant edema if the dip is heavily contaminated. The disease *swelled head*, a form of malignant edema, occurs in young rams 6 months to 2 years old when they are run in bands and fight among themselves.

**Importance**

Outbreaks of malignant edema are probably less common as a result of education of farmers and the availability of vaccines. In the wrong circumstances with improper hygiene severe disease can still occur.

**PATHOGENESIS**

Potent exotoxins are produced in the local lesion and cause death when absorbed into the bloodstream. Locally the exotoxins cause extensive edema and necrosis followed by gangrene.

**CLINICAL FINDINGS**

Clinical signs appear within 6–48 hours of infection. There is always a local lesion at the site of infection consisting of a soft, doughy swelling with marked local erythema accompanied by severe pain on palpation. At a later stage the swelling becomes tense and the skin dark and taut. Empysemata may or may not be present, depending on the type of infection, and may be so marked as to cause extensive frothy exudation from the wound. With *C. novyi* infections there is no emphysema. A high fever (41–42°C, 106–107°F) is always present; affected animals are depressed, weak and show muscle tremor and usually stiffness or lameness. The mucosae are dry and congested and have very poor capillary refill. The illness is of short duration and affected animals die within 24–48 hours of the first appearance of signs. New cases continue to appear for 3–4 days after shearing or other precipitating cause.

When infection occurs at parturition, swelling of the vulva accompanied by the discharge of a reddish-brown fluid occurs within 2–3 days. The swelling extends to involve the pelvic tissues and perineal region. The local lesions are accompanied by a prolonged toxemia and death occurs within 1–2 days.

In *swelled head* of rams the edema is restricted initially to the head. It occurs first under the eyes and spreads to the subcutaneous tissues of the head and down the neck.

In pigs the lesions are usually restricted to the axilla, limbs, and throat and are edematous, with very little evidence of emphysema. Local skin lesions consisting of raised, dull red plaques distended with clear serous fluid containing *C. septicum* and causing no systemic illness may be encountered in pigs at abortions.

In horses, emphysema, detected by palpation or ultrasound, is an early sign.

**CLINICAL PATHOLOGY**

Antemortem laboratory examination of affected farm animals is not usually undertaken, usually because there are carcasses for postmortem examination.

Examination of a Gram-stained smear of aspirated fluid from edematous swellings or swabs from wounds will give an early diagnosis, allowing therapy early in the course of the disease. A PCR has been developed to allow the rapid identification and differentiation of the clostridia associated with malignant edema in livestock.

Hematological examination in horses may show evidence of an immunemediated hemolytic anemia.

**NECROPSY FINDINGS**

Tissue changes occur rapidly after death, particularly in warm weather, and this must be kept in mind when examining postmortem findings. There is usually gangrene of the skin with edema of the subcutaneous and intermuscular connective tissue around the site of infection. There may be some involvement of underlying muscle but this is not marked. The edema fluid varies from thin serum to a gelatinous deposit. It is usually blood-stained and contains bubbles of gas except in *C. novyi* infections when the deposit is gelatinous, clear and contains no gas. A foul, putrid odor is often present in infections with *C. perfringens* and *C. sordelli*.

Subserous hemorrhages and accumulations of serosanguineous fluid in body cavities are usual. In *swelled head* of rams the edema of the head and neck may extend into the pleural cavity and also involve the lungs.

**DIFFERENTIAL DIAGNOSIS**

The association of profound toxemia and local inflammation and emphysema at the site of a wound is characteristic.

- **Blackleg**: The disease is differentiated from blackleg by the absence of typical muscle involvement and the presence of wounds.
- **Anthrax**: In pigs and horses.
- **Photosensitivity** in white-faced sheep with *swelled head*.

**TREATMENT**

Affected animals should be treated as emergency cases because of the acute nature of the disease. Specific treatment requires the administration of penicillin (high doses of crystalline penicillin intravenously, repeated at 4–6-hour intervals) or a broad-spectrum antibiotic. Antitoxin aids in controlling the toxemia but is expensive and must be given very early in the course of the disease. A nonsteroidal anti-inflammatory drug (NSAID) and supportive therapy are recommended. Injection of penicillin directly into and around the periphery of the lesions may be of value in some cases. Local treatment consists of surgical incision to provide drainage, and irrigation with hydrogen peroxide. In horses, early and aggressive treatment with myotomy and fasciotomy, repeated if indicated, coupled with intravenous potassium penicillin is reported to
allow recovery rates approaching 70%. The success rate in treating horses with infections with *C. perfringens* was higher than that with *C. septicum*.1

**CONTROL**

Hygiene at lambing, shearing, castration and docking is essential to the control of the infection in sheep. Vaccination with a specific or multivalent clostridial bacterin-toxoid will prevent the occurrence of the disease in enzootic areas. Penicillin can be given prophylactically to animals at risk for the disease.

**REVIEW LITERATURE**

**REFERENCES**

**BRAXY (BRADSOFT)**

Braxy is an acute infectious disease of sheep in Britain characterized by inflammation of the abomasal wall, toxemia, and a high mortality rate. The disease was common in the early 20th century but now is extremely rare, as reflected in reports by the British Veterinary Laboratories Agency (Veterinary Investigation Centres).

**ETIOLOGY**

*Clostridium septicum*, the common cause of malignant edema in animals, is generally regarded as the causative bacterium.

**EPIDEMIOLOGY**

The disease occurs only in midwinter when there are heavy frosts and snow, and usually only in weaner and yearling sheep. It has occurred in experimental sheep receiving infusions of acetic acid into the abomasum. These were thought to cause abomasitis.1 Adult animals in an enzootic area appear to have acquired immunity. *C. septicum* is a soil-born organism and in many areas can be considered as a normal inhabitant of the ovine intestinal tract.

The disease occurs in the UK and various parts of Europe and has been reported in the southern part of Australia1 but appears to be rare in North America. It is now not of major importance because of its low incidence, although at one time it was sufficiently common to be an important cause of loss in some countries. In affected sheep the case fatality rate is usually about 50% and in enzootic areas an annual loss of 8% has been reported.

**PATHOGENESIS**

Presumably a primary abomasitis, associated with the ingestion of frozen grass or other feed, permits invasion by *C. septicum*, resulting in a fatal toxemia.

**CLINICAL FINDINGS**

There is a sudden onset of illness with anorexia, depression, and high fever (42°C (107°F) or more). The abdomen may be distended with gas and there may be signs of abdominal pain. The sheep becomes recumbent, comatose and dies within a few hours of first becoming ill.

**CLINICAL PATHOLOGY**

Antemortem laboratory examinations are of little value in establishing a diagnosis.

**NECROPSY FINDINGS**

There are localized areas of edema, congestion, necrosis, and ulceration of the abomasal wall. Congestion of the mucosa of the small intestine may also be present and there may be a few subepidermal petechiae. *C. septicum* can be isolated by smear from the cut surface of the abomasal wall or by culture from the heart, blood, and other organs of fresh carcasses. Bacteriologic examinations of tissues must be carried out within an hour of death if the diagnosis is to be confirmed.

Mortality in calves with braxy-like lesions in the abomasum is recorded.2,3

**DIFFERENTIAL DIAGNOSIS**

Clinically the diagnosis of braxy is most difficult. At necropsy the lesions of abomasitis are characteristic, especially if the disease occurs under conditions of severe cold. Overeating on grain may cause local patches of ruminitis and reticulitis but there are no lesions in the abomasum. Braxy may resemble infectious necrotic hepatitis but there are no liver lesions in braxy. The final diagnosis depends on isolation of *C. septicum* from typical alimentary tract lesions.

**TREATMENT**

No treatment has been found to be of value.

**CONTROL**

Management of the flock is important. The sheep should be shorn at night, and fed hay before being let out to the frosted pasture each morning. Vaccination with a formalin-killed whole culture of *C. septicum*, preferably 2 injections 2 weeks apart, is also an effective preventive.

**REFERENCES**

**INFECTIOUS NECROTIC HEPATITIS (BLACK DISEASE)**

**ETIOLOGY**

An acute toxemia of sheep, cattle and sometimes pigs and horses caused by the toxin of *Clostridium novyi* elaborated in damaged liver tissue. Outbreaks usually associated with Fasciobacillary endocarditis.

**EPIDEMIOLOGY**

Adult sheep in good condition. Seasonal prevalence related to the migration of immature liver flukes in the liver.

**CLINICAL FINDINGS**

Sheep - rapid clinical course and often found dead. Short clinical course in cattle and horses with profound depression and toxemia, abdominal pain and peritonitis.

**CLINICAL PATHOLOGY**

None described.

**NECROPSY FINDINGS**

Rapid autolysis, engorgement of subcutaneous vessels with edema. Liver has small areas of yellow-colored necrosis surrounded by a zone of hyperemia.

**DIAGNOSTIC CONFIRMATION**

Finding of *C. novyi* in the typical liver lesion. Fluorescent antibody staining identifies *C. novyi* but not the type.

**TREATMENT**

Parenteral penicillin but high case fatality.

**CONTROL**

Vaccination.

**ETIOLOGY**

The disease occurs in sheep and cattle and rarely in pigs and horses1,4 *Clostridium novyi*, type B, is the cause of...
the disease; it is resident in soil and may be present in the liver of normal animals. The intervention of a necrotic process in the liver, which causes the organism to proliferate and produce lethal amounts of toxin, is commonly stated to be the precipitating cause. C. novyi types A and C are also resident in soil and may invade a carcass postmortem, but do not cause infectious necrotic hepatitis. Type C is nontoxigenic.

The disease has been produced experimentally in sheep by the administration of spores of C. novyi after prior infection with fluke metacercaria. Although field outbreaks of the disease are usually precipitated by invasion of the liver by immature liver fluke it is possible that other causes of local hepatic injury, e.g., invasion by cysts of Cysticercus tenuicollis, and trauma from liver biopsy may precipitate the disease. Thysanosoma actinoides is believed to be a predisposing infection in South America.

Cases are reported in which no specific precipitating lesions are detected and have been advanced as an explanation of sudden deaths in feedlot cattle. C. novyi types A and B have been incriminated as a cause of sudden death in sows.

Epidemiology
Occurrence
The disease is worldwide in distribution but is of particular importance in Australia and New Zealand and to a lesser extent in the UK, the US, and Europe. In sheep, the incidence rate in a given year is usually about 5% in affected flocks but may be as high as 10–30% and in rare cases up to 50%. The disease is always fatal in both sheep and cattle. Details of the incidence in cattle are scanty but the disease is becoming more common in some areas where fluke is being introduced. The disease is rare in horses.

Risk factors
Animal risk factors
Well-nourished adult sheep in the 2-4-year age group are particularly susceptible, lambs and yearlings rarely being affected.

Environmental risk factors
The epidemiological association between liver fluke and C. novyi has been supported by the observation that both are more prevalent in the soil in areas where black disease occurs than in other areas, and the survival of both the bacteria and the fluke is favored by the same type of soil environment.

In temperate climates, a seasonal occurrence is marked because of fluctuation in the liver fluke and host snail population. Outbreaks are most common in the summer or autumn months and cease within a few weeks after frosts occur because of destruction of encysted metacercaria. Exposure to fluke infestation, as occurs when sheep graze on marshy ground during dry summers and drought, is commonly associated with outbreaks of black disease, although they can occur in winter. Sheep removed from a black disease farm may die of the disease up to 6 weeks later because of the time lag required for migration of the flukes.

Heavy irrigation of pastures creates favorable conditions for the development of flukes and may predispose disease. Outbreaks in cattle commonly occur on irrigated farms.

Source of infection
Fecal contamination of the pasture by carrier animals is the most important source of infection, although the cadavers of sheep dead of the disease may cause heavy contamination. Many normal animals in flocks in which the disease occurs carry C. novyi in their livers, not all strains being pathogenic. The spread of infection from farm to farm occurs via these sheep and probably also by infected wild animals and birds and by the carriage of contaminated soil during flooding.

Other species
There is little information of the epidemiology of the disease in the horse, although prior administration of an anthelmintic may be a risk factor. C. novyi can be a significant cause of sudden death of adult pigs. In some herds the disease is more common in older sows (average parity 5.6 litters) with the highest prevalence in the spring months.

Pathogenesis
Spores of C. novyi are ingested and carried to the liver in the lymphatic system; the organism can be isolated from the livers of normal animals. Under local anaerobic conditions, such as occur in the liver when migrating flukes cause severe tissue destruction, the organisms already present in the liver proliferate, liberating alpha toxin, which is necrotic and causes local liver necrosis and more diffuse damage to the vascular system. The nervous signs observed may be due to this general vascular disturbance or to a specific neurotoxin.

Clinical Findings
Sheep
Affected sheep commonly die during the night and are found dead without having exhibited any previous signs of illness. When observation is possible, clinically affected sheep are seen to segregate from the rest of the flock, lag behind and fall down if driven. There is fever (40–42°C, 105–107°F), which subsides to a premonital (subnormal) level, and some hyperesthesia; respiration is rapid and shallow; the sheep remains in sternal recumbency and often dies within a few minutes while still in this position. The course from first illness to death is never more than a few hours and death usually occurs quietly, without evidence of struggling.

Cattle
Clinical findings are the same in cattle as in sheep but the course is longer, the illness lasting for 1–2 days. Outstanding clinical findings in cattle include a sudden severe depression, reluctance to move, coldness of the skin, absence of rumen sounds, a low or normal temperature, and weakness and muffling of the heart sounds. There is abdominal pain, especially on deep palpation of the liver, and the feces are semifluid. Periorbital edema may also develop.

Horses
In the horse, the syndrome presents as a peritonitis accompanied by severe and progressive toxemia and manifests with depression, reluctance to walk, pain on palpation of the abdomen, frequent straining and recumbency. Fluid from abdominal paracentesis has a profound increase in nucleated cells and protein. Death occurs within 72 hours of onset of the disease.

Clinical Pathology
Antemortem laboratory examinations are not usually possible because of the peracute nature of the disease, and there is no body of information for this disease.

 Necropsy Findings
Bloodstained froth may exude from the nostrils. The carcass undergoes rapid putrefaction. There is pronounced engorgement of the subcutaneous vessels and a variable degree of subcutaneous edema. "The dark appearance of the inside of the carcass may give rise to the name black disease." Gelatinous exudate may be present in the fascial planes of the abdominal musculature. Bloodstained serous fluid is always present in moderate quantities in the pericardial, pleural, and peritoneal cavities. Subendocardial and subepicardial hemorrhages are frequent.

The liver is swollen, gray-brown, and exhibits characteristic areas of necrosis. These are yellow areas 1–2 cm in diameter and are surrounded by a zone of bright red hyperemia. They occur mostly under the capsule of the diaphragmatic surface of the organ but may be more deeply seated and can easily be missed unless the liver is sliced carefully. In cattle they are often linear in shape and may be...
difficult to find. There is usually evidence of recent invasion by liver fluke, with channels of damaged liver tissue evident on the cut surface of the liver. These may be mistaken for subcapsular hemorrhages when viewed from the surface. Mature flukes are not ordinarily observed. Histologically, the liver lesion consists of a central tract of eosinophilic inflammation (due to fluke migration) surrounded by a zone of coagulation necrosis and an outer rim of infiltrating neutrophils. Gram-positive bacilli can easily be demonstrated within the lesion.

A diagnosis of black disease requires the culture of *C. novyi* from the typical liver lesion and the demonstration of preformed toxin in the peritoneal fluid and/or the liver lesion from a fresh carcass. Autolysis rapidly clouds the postmortem picture of the liver lesion and the demonstration of toxin-producing strains of *C. novyi* B. These strains are detected in livers by the fluorescent antibody technique and this may lead to a false-positive identification of black disease.

Fluorescent antibody techniques are almost as accurate and much less time-consuming than traditional anaerobic culture methods. An ELISA for beta toxin in intestinal contents has been described and PCR techniques for better identification of toxin-producing strains of *Clostridium* are available.

Unusual lesions, such as a large area of inflammation in the wall of the abomasum and congestion of the subcutaneous tissue and muscle in the shoulder and withers, have been observed in some cattle dying of the disease.

**Samples for confirmation of diagnosis**
- Bacteriology – liver in air-tight container, four impression smears from periphery of lesion (anaerobic CULT, FAT)
- Histology – fixed liver.

**DIFFERENTIAL DIAGNOSIS**
- Acute fascioliasis in sheep can cause heavy mortality due to massive liver destruction at the same time and under the same conditions as does black disease
- Other clostridial disease – blackleg, malignant edema
- Anthrax

**TREATMENT**
No effective treatment is available. In cattle and horses the longer course of the disease suggests the possibility of control-

ling the clostridial infection by the parenteral use of penicillin or broad-spectrum antibiotics but reported cases have high case fatality.

**CONTROL**
- **Vaccination** with an alum-precipitated toxoid is highly effective and can be carried out during the course of an outbreak. The mortality begins to subside within 2 weeks. On an affected farm the initial vaccination is followed by a second vaccination 4–6 weeks later and subsequently by annual vaccinations. To provide maximum immunity at the time when the disease is most likely to occur, vaccination as a prophylactic measure should be carried out in early summer.
- **Control of the disease** should also be attempted by **control of the liver fluke**. The host snail must be destroyed in streams and marshes by the use of molluscid and the flukes eliminated from the sheep by treatment with flukicides. Pasteurellosis contamination from cadavers should be minimized by burning the carcasses.

**REVIEW LITERATURE**

**REFERENCES**

**BACILLARY HEMOGLOBINURIA**

**ETIOLOGY**
*Clostridium haemolyticum* (C. novyi type D) is a soil-borne anaerobe. The longevity of the spores in soil is unknown but the organism has been isolated from bones a year after the death of an animal from bacillary hemoglobinuria. In infected areas the organism is often found in the livers of healthy cattle. Under anaerobic conditions the organism grows and produces a necrotic and hemolytic toxin that is responsible for the clinical disease. Damage to the liver from telangiectasia, necrobacillosis caused by *Fusobacterium necrophorum*, and fascioliasis have been suggested as precipitating causes.

The disease has been produced experimentally by injecting calves orally and inducing liver damage by liver biopsy, or by implanting the organism in the liver. Cultures of the organism produce severe muscle necrosis and hemoglobinuria when injected intramuscularly into cattle and experimental animals.

**EPIDEMIOLOGY**

**Occurrence**
Bagillary hemoglobinuria has been reported principally from the western part of the USA, although the disease has also been observed in the southern states, Canada, Mexico, Venezuela, Chile, Turkey, Australia, New Zealand, the United Kingdom, and the Netherlands. The disease is not common but on affected farms death losses, which are usually less than 5%, may reach as high as 25%.

**Risk factors**
Animal risk factors
Cattle are the usual species involved although occasional cases occur in sheep and rare cases in pigs. As is the case in many clostridial diseases, animals in good condition are more susceptible.

**Environmental risk factors**
Bagillary hemoglobinuria is a disease of the *summer and autumn* months. A primary association occurs with pastures that also are associated with the occurrence of liver fluke although other, less determined risk factors obtain. The highest
incidence of bacillary hemoglobinuria is on irrigated or poorly drained pasture, especially if the soil is alkaline in reaction. Some outbreaks have occurred in feedlots where hay cut from infected fields was fed.

The disease is rare on dry, open range country but does occur in range country where cattle have access to swales with areas naturally irrigated by springs or streams. Heavy mortalities may occur when cattle from an uninfected area are brought on to an infected farm, cases beginning to occur 7-10 days later.

The disease is spread from infected to noninfected areas by flooding, natural drainage, contaminated hay from infected areas, or carrier animals. The carriage of bones or meat by dogs or other carnivores could also affect spread of the infection. Contamination of pasture may occur from feces or from decomposing cadavers.

PATHOGENESIS
Although attempts to produce the disease by feeding the organism have been unsuccessful it is probable that under natural conditions in endemic areas invasion occurs from the alimentary tract after ingestion of contaminated material. Migrating flukes are the primary factor leading to liver necrosis and the establishment of anaerobic conditions in the liver that will lead to the multiplication of the causative organism. Invasion of the liver by *Cysticercus tenuicollis* and other causes of liver damage can also lead to the disease. As in black disease of sheep, the bacteria are carried to the liver and lodge there until damage to the parenchyma of the liver and the resulting hypoxia create conditions suitable for their proliferation. The development of an organized thrombus in a subterminal branch of the portal vein produces the large anemic infarct that is characteristic of the disease. Most of the bacteria are to be found in this infarct and, under the anaerobic conditions, the necrotic and hemolytic beta toxin is released systemically to result in toxemia, generalized vascular damage and intravascular hemolysis.

CLINICAL FINDINGS
Animals brought into contact with the infection in endemic areas seldom develop disease until 7-10 days later. The illness is of short duration and cattle at pasture may be found dead without signs having been observed. More often there is a sudden onset, with complete cessation of rumination, feeding, lactation, and defecation. Abdominal pain is evidenced by disinclination to move and an arched-back posture. Grunting may be evident on walking. Respiration is shallow and labored and the pulse is weak and rapid. Fever (39.5-41°C, 103-106°F) is evident in the early stages but the temperature subsides to subnormal before death. Edema of the face is a common finding. The feaces are dark brown; there may be diarrhea with much mucus and some blood. The urine is dark red. Jaundice is present but is never very obvious. The duration of the illness varies from 12 hours in dairy cows in advanced pregnancy to 4 days in dry stock. Pregnant cows often abort. Severe dyspnea is evident just before death. The disease in sheep presents with similar signs.

CLINICAL PATHOLOGY
The red color of the urine is due to the presence of hemoglobin: there are no free red cells. In the later stages there is anemia, the erythrocyte count being depressed to between 1 and 4 × 10^10/L and the hemoglobin to 3-8 g/L. Leukocyte counts vary considerably from 6700-34 800 × 10^9/L. Differential counts vary similarly, with a tendency to neutrophilia in severe cases. Serum calcium and phosphorus levels are normal but blood glucose levels may be elevated (100-120 mg/dL) in some cases.

Blood cultures during the acute stages of the disease may be positive. Serum agglutinins against *C. haemolyticum* may be detectable at low levels (1:25 or 1:50) during the clinical illness and, if the animal recovers, rise to appreciable levels (1:50 to 1:800) a week later. Titer greater than 1:400 are usual at this time. A positive agglutination test is not conclusive evidence of the presence of the disease.

NECROPSY FINDINGS
Rigor mortis develops quickly. The peritoneum is soiled with bloodstained urine and feces. Subcutaneous, gelatinous edema, which tends to become crepitant in a few hours, and extensive petechial or diffuse hemorrhages in subcutaneous tissue are characteristic. There is a variable degree of jaundice. Excessive amounts of fluid, varying from clear to bloodstained and turbid, are present in the pleural, pericardial, and peritoneal cavities. Generalized subserous hemorrhages are also present. Similar hemorrhages appear under the endocardium. Hemorrhagic abomasitis and enteritis are accompanied by the presence of bloodstained ingesta or free blood. The characteristic lesion of bacillary hemoglobinuria is an ischemic infarct in the liver. One or more may be present in any part of the organ and vary from 5-20 cm in diameter. The infarct is pale, surrounded by a zone of hyperemia, and has the general appearance of local necrosis. Red urine is present in the kidneys and bladder and petechiation is evident throughout the kidney.

C. *haemolyticum* can be isolated from the liver infarct and many other organs from a fresh carcass, but postmortem invaders quickly obscure its presence. A positive fluorescent antibody test on impression smears taken from the hepatic zone around the liver infarct and stained with FITC-labeled rabbit anti-*C. novyi* antiserum will confirm the presence of *C. novyi*-type organisms but cannot differentiate type B from type D. A PCR test to identify toxin-producing genotypes of *Clostridium* spp. may assist in the identification of isolates.

Samples for confirmation of diagnosis
- Bacteriology – tissue from edge of liver infarct, placed in an airtight container; four air-dried impression smears from lesion border (anaerobic CULT, FAT)
- Histology – fixed liver lesion, kidney.

Differential Diagnosis
The diagnosis of bacillary hemoglobinuria is largely a question of differentiation from other diseases in which hemoglobinuria, myoglobinuria, and hematuria are cardinal signs. In an animal found dead differentiation from other clostridial diseases and anthrax may be required.

- Acute leptospirosis
- Postparturient hemoglobinuria
- Hemolytic anemia caused by cruciferous plants
- Babesiosis and anaplasmosis
- Enzootic hematuria
- Chronic copper poisoning (sheep)

TREATMENT
Specific treatment includes the immediate use of penicillin or tetracyclines at high doses and antitoxin serum if available. Prompt treatment is essential: provided that the serum is administered in the early stages of the disease, hemoglobinuria may disappear within 12 hours.

Supportive treatment – including blood transfusion, parenteral fluid, and electrolyte solutions – is of considerable importance. Care is required during treatment and examination, as undue excitement or exercise may cause sudden death. Bulls should not be used for service until at least 3 weeks after recovery because of the danger of liver rupture. Convalescence is often prolonged and animals should be protected from nutritional and climatic stress until they are fully recovered. Hemopoesis should be facilitated by the provision of mineral supplements containing iron, copper, and cobalt.

CONTROL
A formalin-killed whole culture adsorbed on aluminum hydroxide gives good
protection for a year in cattle. Vaccination is carried out 4–6 weeks before the expected occurrence of the disease. Annual revaccination of all animals over 6 months of age is necessary in enzootic areas. In some locations of extreme risk a second vaccination during the grazing season is recommended. To obviate the local reaction that occurs at the site of injection the inoculum may be administered in a suitable vehicle along with the principle antigen.

**REFERENCES**

**ENTERIC DISEASE ASSOCIATED WITH CLOSTRIDIUM PERFRINGENS**

Clostridium perfringens resides in the intestinal tract of domestic animals and can produce a number of toxins that result in enteric and histotoxic disease. C. perfringens isolates are classified into one of five types, types A–E, depending on their ability to produce the four major lethal toxins: the alpha, beta, epsilon, and iota toxins. The activities of these major lethal toxins are the basis of the pathogenesis of the classical enterotoxemias attributed to this organism and described below. More recently, it has been recognized that C. perfringens produces other toxins of probable importance in animal disease. These include an enterotoxin and a cytotoxic beta-2 toxin, the latter encoded by the cdp2 gene.1,2

The amino acid sequence of the beta-2 toxin has little homology with that of the major beta toxin and they are only weakly related immunologically, but the biological activity of the two toxins is similar and both are cytotoxic and cause hemorrhagic necrosis of the intestinal wall.3 The importance of enterotoxin and the beta-2 toxin to animal disease is still uncertain. Both appear important in the cause and pathogenesis of enteric disease in pigs.1,2,4,5

The beta-2 toxin may have importance in enterocolitis in foals and adult horses as Cbp2-positive C. perfringens type A has been isolated from diarrheic foals and adult horses; however, the significance of these isolations to the disease is still not fully determined.2,6

**REFERENCES**

**ENTEROTOXEMIA ASSOCIATED WITH CLOSTRIDIUM PERFRINGENS TYPE A**

The role of C. perfringens type A in the pathogenesis of diseases of animals is uncertain because the organism forms part of the bacterial flora of the alimentary tract in many normal animals. However, there are an increasing number of reports that attribute disease and mortality to this organism. The validity of these attributions remains to be fully determined but they are listed below.

Enterocolitis in horses

Enterocolitis in foals and adult horses is an etiologically poorly defined syndrome. Enterocolitis associated with *C. difficile* is one cause and is covered under that heading elsewhere in this text. In addition, enterocolitis associated with *C. perfringens* type C is covered under that heading. There remains a syndrome of enterocolitis that is manifested with enteritis, diarrhea and colic, and a high case fatality, and one that is diagnosed most often at postmortem. It appears to occur worldwide and although occurrence is sporadic, there is the perception that there is an increasing prevalence of this disease. A study of risk factors in the western USA found that stock horse breeds were more at risk and that the presence of other livestock on the farm, and housing in a stall or dry lot for the first 3 days of life, was associated with increased risk. Other studies have implicated barn hygiene as a factor that should be considered in preventive procedures.

There have been a number of clostridial species that have historically been associated with the syndrome besides *C. perfringens* type A. In some cases this association has been by identification of type-specific toxin in the intestine of the affected horse but in others it has been made by the presence of large numbers of the incriminated organism in affected animals in comparison to occurrence and numbers in normal horses. This association has risk as the number of clostridia in the intestine can be influenced by diet, clostridia can multiply in the intestine following death, and they can exist in different forms that may be variably isolated with different cultural techniques.

Equine intestinal clostridiosis

A syndrome historically named equine intestinal clostridiosis has been attributed to intestinal infection with *C. perfringens* type A in adults. The syndrome was characterized by an acute profuse watery diarrhea with high mortality in adult horses and the demonstration of large numbers of *C. perfringens* type A in the intestine at postmortem. It was described as occurring in horses with hemorrhagic cecitis and colitis similar to colitis X, in horses collapsing and dying following exercise, and in other circumstances. Diarrhea and death were reproduced with massive (biologically implausible) oral challenge with broth cultures of these organisms and colic and hemorrhagic gastroenteritis were produced by intravenous injection of ponies with *C. perfringens* type A enterotoxin. The evidence of an association of *C. perfringens* type A with disease in these early studies was equivocal but *C. perfringens* type A can be isolated from both foals and adults with enterocolitis. However, isolation from this disease and causal association remain to be determined. *C. perfringens* is common in the environment of foals and one study in over 128 healthy foals found that *C. perfringens* type A could be isolated from the feces of the majority of foals at 3 days of age. *C. perfringens* with the gene for beta-2 toxin expression was found in the feces of 28 foals and with the enterotoxin gene in five foals. Consequently the isolation of *C. perfringens* type A expressing the gene for beta-2 toxin does not constitute a causal diagnosis. There is, however, a suggestion that *C. perfringens* type A that expresses the gene for beta-2 toxin may be the particular subset of this isolate that is responsible for this disease.

Enteritis in piglets

*Perfringens* type A is associated with diarrhoeal food poisoning in humans and a similar diarrhea in pigs may be produced by infection with this organism. The disease is manifest with a watery yellow diarrhea occurring in piglets under 5 days of age, usually in the first 3 days of age, and a high morbidity but low case fatality. At postmortem there is a mild enterocolitis and villous atrophy. It is controlled with sanitation procedures or with the type of prophylactic procedures used with enterotoxemia associated with *C. perfringens* type C.

Hemorrhagic enterotoxemia and hemolytic disease in cattle, sheep, and goats

There are reports of a highly fatal hemolytic disease in cattle, sheep, and lambs (yellow lamb disease), of an acute hemorrhagic enteritis in calves and adult cattle, and of an acute hemolytic enterotoxemia in foals and goats, associated with the presence of large numbers of *C. perfringens* type A in the intestine. These reports have some credibility because of the activity of the primary toxin of *C. perfringens* type A, alpha toxin, which possesses phospholipase C and sphingomyelinase activity and consequently hemolytic action. Also the presence of beta-2 toxin in these strains may contribute to the pathogenicity. Some credibility is also engendered by reports, albeit occasional, of similar syndromes in different geographical areas and by different institutes.

In the hemolytic disease there is an acute onset of severe depression, collapse, mucosal pallor, jaundice, hemoglobinuria, dyspnea, and the presence of severe abdominal pain. Temperatures range from normal to 41°C (106°F). The disease is highly fatal, most affected animals dying within 12 hours of the onset of illness, although occasional animals survive for several days. Large numbers of *C. perfringens* and the presence of the specific toxin in feces is used to make a presumptive diagnosis. At necropsy the cardinal features are pallor, jaundice, and hemoglobinuria. The kidneys are swollen, dark brown in color, and may contain infarcts; the liver is pale and swollen and there may be hydropericardium and pulmonary edema. There is extensive necrosis of the small intestine. Clostridia dominate the bacterial population of the small intestine, as indicated by smears made from the contents, and alpha toxin is present in large quantities. The toxin is present in large quantities in the intestine, which is indicative of the existence of the disease.

The syndrome is very similar to that associated with chronic copper poisoning and leptospirosis in calves.

In the hemorrhagic enteritis of calves, foals, and adult cattle the syndrome observed is indistinguishable from that associated with *C. perfringens* types B and C. The disease in adult cattle occurs most commonly in the period shortly after calving. The experimental disease in lambs and calves produced by the intravenous injection of toxin is characterized by transitory diarrhea and hyperemia of the intestinal mucosa. Type A antiserum has been effective in prevention of the disease in calves and a formalinized vaccine has shown some immunizing capacity in sheep.

Abomasal ulcer

*C. perfringens* type A has been suspected in the etiology of abomasal ulcers7 in suckling beef calves in western North America and less commonly elsewhere, but there is no compelling evidence for this.

Jejunal hemorrhage syndrome in cattle

*C. perfringens* type A has been proposed as a cause of this disease, largely based on the isolation of this organism from the intestine of affected animals.

This organism is present in the intestinal tract of normal animals and, while it is possible that a subset of Cbp2-positive, beta-2 toxin-producing *C. perfringens* type A organisms are responsible for this disease, there is little convincing evidence for an association with current information.

REFERENCES

by these organisms occur in animals in the first few days of life, with the exception of the disease struck in sheep. Their predominance in very young animals may be due to the immaturity of their alimentary tracts, the beta toxin being readily inactivated by trypsin, and because of the ready colonization of the gut by C. perfringens in the absence of a mature intestinal flora. It is probable that many animals become subclinically challenged but do not show clinical illness, as antitoxin has been detected in clinically normal animals. The bacteria are capable of forming spores that survive for long periods. In general, rapidly growing, well-nourished animals are most susceptible. The toxins produced are alpha, beta, and epsilon in type B, and alpha and beta in type C.

Beta-2 toxin is also produced by some of these organisms and appears important to their pathogenicity in pigs and horses. There are subtypes of these organisms with differing toxin production abilities. Alpha and iota toxin are produced by type E, which is a rare cause of enterotoxemia in calves and lambs.

The diseases that are produced by these organisms in the different animal species, and the organisms’ names, are as follows:

- **Lamb dysentery** associated with C. perfringens type B. An enterotoxemia of young lambs is also associated with C. perfringens type C.
- **Goat enterotoxemia** associated with C. perfringens type C and rarely by type B.
- **Necrotic enteritis of pigs, pig enterotoxemia** associated with C. perfringens types C and less commonly by type B.
- **Foal enterotoxemia** associated with C. perfringens types C and B.
- **Calf enterotoxemia** associated with C. perfringens types B and C.
- **Struck**, associated with C. perfringens type C, affects adult sheep, particularly when feed is abundant.

**EPIDEMIOLOGY**

**Lamb dysentery and type C enterotoxemia**

**Occurrence**

Lamb dysentery associated with type B occurs in Great Britain, Europe, and South Africa and is an important disease in these countries. In contrast, this disease is rare or absent in Australia, New Zealand, North America, and Japan, where type C infections are more important. The geographical variation may be due to variation in the occurrence of the types of C. perfringens. Lamb dysentery does not occur in New Zealand and C. perfringens type B has not been found in sheep or soil samples in that country.

**Type C enterotoxemia** in lambs and goats occurs particularly with sheds lambing in North America and where there is close stocking of ewes and lambs at lambing. It is also recorded in Australia.

Animal and environmental risk factors

In lamb dysentery, the incidence of clinical disease in groups of lambs may reach as high as 20–30%. In an outbreak, the disease initially affects 1–4-day-old lambs and the clinical course is very short. A characteristic of the disease is the tendency for an increase in incidence rate as lambing progresses and for the involvement of older lambs, up to 2–3 weeks of age, which survive for longer periods. The case fatality rate approaches 100%.

In Great Britain lamb dysentery occurs primarily in the hill breeds of sheep, breeds that have a small litter size but good milk production, and the appearance of the disease in a particular year appears to be related to weather conditions that allow sufficient pasture growth to produce profuse lactation in the ewes. The time of onset of the disease in a lambing season is related to the weather conditions that predispose to its occurrence.

**Type C enterotoxemia** in lambs and goats is prevalent in cold weather and on farms where ewes are kept closely confined in small yards or fields for lambing and kidding. Gross contamination of the surroundings with the causative bacteria is likely to occur in these circumstances. The disease can occur as an outbreak with an attack rate of 15–20% and a case fatality that approaches 100%. Type C enterotoxemia is more common in single-bred lambs and is largely restricted to lambs 12 hours to 4 days of age. Sporadic disease occurs in orphan or ‘bummer’ lambs reared on milk replacer, which appear particularly at risk and may develop the disease at up to 2 weeks of age.

**Necrotic enteritis of pigs**

**Occurrence**

Necrotic enteritis is an important disease of piglets, particularly in intensive pig units. It occurs in most countries but has been reported most commonly from certain areas in the USA, Europe, and the UK.

Animal and environmental risk factors

The organisms are recoverable from the skin of sows and the feces of affected piglets, and infection probably occurs during suckling. The number of piglets affected varies between herds and between litters. The disease may occur sporadically in a piggery but commonly occurs as an outbreak affecting several litters within a given time period. Pigs up to 7 days of age are most commonly affected and susceptibility to disease and

**ETIOLOGY**

The general etiology of these diseases is given below but, because of differing circumstances of occurrence, the description of the epidemiology of these diseases is given separately according to animal species.

The causative clostridia occur commonly in soil, the animals’ housing environment and the alimentary tract of healthy animals, and management factors precipitate disease. The diseases produced...
its severity decreases with age. Peracute disease with rapid death occurs in piglets affected at 1–2 days of age, whereas piglets affected at 1–2 weeks show a more protracted clinical course. The case fatality is high and in severe outbreaks 80% of piglets at risk may die. The disease tends to become endemic in pig units and to recur on the same premises in succeeding years.

Insufficient cleaning and disinfection of farrowing pens, the housing of pigs on concrete, and the routine use of antibiotics to which C. perfringens is resistant, such as the aminoglycosides, have been proposed as risk factors for buildup of infection in swine units.

Enterotoxemia in foals

Enterotoxemia in foals has been associated with both C. perfringens type B and type C. Type C predominates in reports from North America. Reports are of a single foal on a farm being affected and the disease generally occurs in foals under 7 days of age, although enterotoxemia associated with type B has been recorded in a 4-week-old foal. The factors that predispose to disease in foals are poorly defined.

Enterotoxemia in calves

Enterotoxemia due to C. perfringens type B or C is uncommon in calves. The disease usually occurs as outbreaks of severe dysentery with some deaths in calves 7–10 days old, although calves up to 10 weeks of age may be affected.

Struck in sheep

Struck in adult sheep on good pasture in spring is limited in its occurrence to certain localities in Britain and is rarely reported.

Pathogenesis

The organism is ingested from soil and fecal contamination on the surface of the dam’s udder. It proliferates and attaches to the surface of the epithelial cells of the intestinal villus but toxin production and mucosal damage may precede attachment. The factors that allow proliferation and attachment are poorly understood. Toxigenic strains of C. perfringens types B and C both produce both alpha and beta toxin.

The alpha toxin is a lethal toxin and is produced in varying amounts by isolates of both types. It is a phospholipase, and hydrolysis of membrane phospholipids in erythrocytes, platelets, leukocytes, and endothelial cells results in cell lysis or other forms of cytotoxicity. The beta toxin causes increased capillary permeability and may facilitate its uptake from the intestine. Beta toxin is a nercotyzing toxin and initially produces damage to the microvilli with degeneration of mitochondria, with eventual destruction and desquamation of the intestinal epithelial cells and the production of a hemorrhagic enteritis and ulceration of the intestinal mucosa.

The age incidence of these diseases may be partially explained by the observation that beta toxin is highly sensitive to inactivation by trypsin, which is a component of normal pancreatic proteases. Colostrum contains a trypsin inhibitor and trypsin is decreased or absent in affected pigs. Experimentally administered soybean flour used as a protease inhibitor converts experimentally induced clostridial enteritis from a nonfatal to a fatal disease.

Clinical Findings

Lamb dysentery can be manifest by sudden death without premonitory signs in peracute cases. In the more common acute form, there is loss of sucking drive and severe abdominal pain manifest by bleating, stretching, and looking at the abdomen. Lambs pass brown, fluid feces sometimes containing blood, and dehydration is often accompanied by painful straining. Death usually occurs after a period of recumbency and coma and within 24 hours of the onset of illness. On farms where the disease has become established, cases may occur in older lambs up to 3 weeks of age and occasional cases may survive for several days. A chronic form of the disease in older lambs is referred to as ‘pine’, and manifest with chronic abdominal pain and reluctance to suck, but no diarrhea, is recognized and responds to treatment with specific antiserum.

Necrotic enteritis in piglets is also manifest with rapid death in young animals and more prolonged disease in slightly older piglets. Affected pigs become dull and depressed and exhibit diarrhea, dysentery, and gross reddening of the anus. The feces of piglets affected within 2–3 days of life is watery and initially yellow but in a proportion of pigs will become hemorrhagic and red-brown in color, and contain necrotic debris. The clinical course in piglets affected at this age is usually less than 24 hours; they rapidly become dehydrated, hypoglycemic, hypothermic, and comatos. Piglets affected at an older age have a fluid, yellow-colored diarrhea and blood may not be evident. Frequently the majority of litters born during an outbreak will be affected, although affected litters may include some normal pigs. Occasionally weaned pigs are affected. Acute outbreaks in herds may be followed by the occurrence of chronic necrotizing enteritis.

Foals with enterotoxemia associated with C. perfringens type B or C show evidence of severe depression, pronounced toxemia, and marked abdominal pain. Affected foals are a few days old and have an acute attack of collapse with bloody feces, subnormal temperature, fast pulse, and respiratory rate, and death within a few hours. Colic may be evident and a major differential diagnosis is an acute intestinal accident. The clinical course is very short and diarrhea does not occur in many cases. There are limited descriptions of the clinical disease in foals because of its sporadic occurrence and rapid course.

In calves signs include diarrhea, dysentery, and acute abdominal pain accompanied by violent bellowing and aimless running. There may be additional nervous signs, including tetany and opisthotonos. In very acute cases, death occurs in a few hours, sometimes without diarrhea being evident. In less severe cases, the illness lasts for about 4 days and recovery is slow, usually requiring 10–14 days.

Struck in adult sheep is manifested only by sudden death, clinical signs not being observed beforehand. Occasionally death is preceded by abdominal pain and convulsions.

Clinical Pathology

The disease in all species is so acute and so highly fatal that the diagnosis is usually made on necropsy material. Antemortem laboratory examinations are not widely used in diagnosis and there is no database but the predominance of clostridia in a fecal smear may suggest a diagnosis of hemorrhagic enterotoxemia. Specific antitoxins are detectable in the sera of recovered animals. A severe hypoglycemia has been observed in baby pigs dying of the disease but this is not specific in this infection.

Necropsy Findings

The major lesion in all species is a hemorrhagic enteritis, with ulceration of the mucosa in some cases. With type B infections the lesions occur as localized areas of necrosis, usually most evident in the ileum. The intestinal mucosa is dark red and the ulcers are large (up to 2.5 cm in diameter) and almost transmural. Intestinal contents are bloodstained and may contain fibrin clots.

With type C infection the areas of necrosis are more extensive, involving entire segments of small intestine and often inducing a peritonitis. Subendocardial and subepicardial hemorrhages are common in ruminants dying of enterotoxemia. If the necropsy of adult sheep is delayed for several hours, the fascial tissues may develop the appearance of malignant edema. Carcasses of 7–10-old-old pigs may lack the severe hemorrhagic enteritis typical of the disease in newborn pigs. The less acute disease course in this older age group often results in a yellow,
fibrous deposit on the intestinal mucosa, accompanied by large quantities of watery, lightly bloodstained ingesta in the lumen.

In general, the histological features of gut segments affected by these types of enterotoxemia include mucosal hemorrhage, necrosis, fibrin exudation, and a neutrophilic infiltrate. Large numbers of bacterial rods line the luminal surface of these lesions. Unfortunately, postmortem autolysis frequently eliminates the possibility of identifying some of the features.

Smears of intestinal contents can be stained and examined for large numbers of clostridium-like organisms, and filtrates of the contents may be tested for toxin content. Definitive typing of the clostridia has traditionally been via in vivo assays but these are undesirable on humanitarian grounds and are being replaced by immunoassays such as ELISA and passive latex agglutination. A rapid passive latex agglutination test (RPLA) permits confirmation of the presence of alpha toxin but does not permit distinction between the various types of C. perfringens capable of producing the toxin. A multiplex PCR test enables characterization of C. perfringens isolates based on their genotypic potential for toxin production. PCR techniques detect the genes encoding the major toxins and are promoted for replacing in vivo tests for toxin. The PCR test can differentiate toxigenic clostridial isolates recovered from diseased animals and nontoxigenic isolates recovered from normal animals.

**Samples for confirmation of diagnosis**
- Bacteriology – 20–30 mL of intestinal content, frozen in a glass or plastic leakproof container (latex agglutination, anaerobic CULT, bioassay, PCR), air-dried smears of mucosal surface from several levels of small intestine (cyto – Gram stain)
- Histology – fixed ileum, jejunum (several segments of each).

**TREATMENT**
In individual cases the disease is often too acute for effective therapy but fluid and supportive therapy are indicated. Hyperimmune serum is the specific therapy and the major therapy of value. Oral and parenteral administration of penicillin may prevent further proliferation of organisms and production of toxins.

**CONTROL**
Vaccination, preferably with type-specific toxoid or bacterin, is the specific preventive measure.

**Outbreaks**
In outbreaks, because of the need for rapid action, it is usually necessary to proceed with vaccination before typing of the organism can be carried out. Cross-protection occurs between C. perfringens types B and C because the beta toxin is produced by both strains and is central to the disease produced by both strains. Lamb dysentery antiserum will protect against Type C infections. Type C toxoid and antiserum are also available.

When an outbreak occurs all pregnant animals should be vaccinated to provide colostral immunity to their progeny. However, vaccination of the dam requires a period of at least 2 weeks before there is sufficient protective antibody in colostrum. As a result there will be a period of time between vaccination and protection of the newborn, and animals born during this period need to be provided with protection by the administration of specific antiserum. Antiserum will protect susceptible animals and should be administered immediately after birth. An alternate, and sometimes more cost-effective procedure, is to administer benzathine or benzathamine penicillin G or depot amoxicillin at birth and to repeat as required during the period of susceptibility.

**Long-term control**
Long-term control rests with vaccination of the dams. To initiate the program two injections of vaccine are necessary 1 month apart, the second injection being given 2–3 weeks before parturition. For the prevention of lamb dysentery the two vaccinations of ewes may be spaced 2–5 weeks apart and the second injection can be given as early as 2 months before lambing, thus avoiding handling of heavily pregnant ewes. In subsequent years, ewes require only one booster injection immediately prior to parturition.

For the protection of piglets the sow is vaccinated 5 and 3 weeks before farrowing, but vaccination at mating, repeated 2–3 weeks before farrowing, is adequate.

Attention should be given to the unitage of the antigen or antitoxin present in clostridial toxoids and antiserum. These vary widely and the manufacturer’s instructions should be followed closely. Anaphylaxis may occur with some antiserum of equine origin and treated animals should be kept under close observation for 24 hours and treated quickly if signs of dyspnea and muscle shivering occur.

In the face of an outbreak the lambing area should be moved, or with piglets the farrowing rooms vigorously cleaned and disinfected. The feeding of bacitracin (300 mg/kg of feed) or salinomycin (60 mg/kg feed) to the sow for 1–2 weeks before farrowing has been shown to reduce disease incidence, possibly by decreasing the level of excretion of C. perfringens by the sow.

**REFERENCES**
ENTEROTOXEMIA ASSOCIATED WITH CLOSTRIDIUM PERFRINGENS TYPE D (PULPY KIDNEY, OVEREATING DISEASE)

**Synopsis**

**Etiology** An acute toxemia of ruminants associated with the proliferation of Clostridium perfringens type D in the intestines and the liberation of epsilon toxin that produces vascular damage and the damage to the nervous system typical of this disease.

**Epidemiology** Lambs 3–10 weeks of age and lambs and calves after weaning. Goats of all ages. Affected animals in good condition and on a rising plane of nutrition.

**Clinical findings** The disease in lambs and calves and young goats has a rapid course with diarrhea, depression, and convulsions. At this age animals are often found dead. Adult goats show more chronic disease with abdominal pain and bloody diarrhea.

**Clinical pathology** Hypoglycemia and glycosuria in sheep.

** Necropsy findings** None specific to all cases. Sheep and goats may have gross or histological areas of malacia in internal capsule, lateral thalamus and cerebellar peduncles.

**Diagnostic confirmation** Epidemiology, clinical and necropsy findings, demonstration of epsilon toxin.

**Treatment** Anti-epsilon antitoxin

**Control** Feed restriction, antitoxin, vaccination.

ETIOLOGY

Enterotoxemia results from the proliferation of C. perfringens type D in the small intestine. This organism produces a number of toxins, of which the epsilon toxin is the most important and results in vascular damage and the damage to the nervous system typical of this disease. The presence of C. perfringens type D in the intestine does not in itself result in disease unless other factors intercede that promote proliferation and the production of toxin. The natural habitat of the organism is in the intestine and in soil contaminated by feces, although it does not persist in soil for long periods of time.

EPIDEMIOLOGY

**Occurrence**

Enterotoxemia associated with C. perfringens type D is a disease of ruminant animals, primarily of lambs, and is worldwide in its distribution. The common practice of vaccination against this disease has reduced its prevalence but it is still a common disease.

While most common in lambs, it is also an important disease of calves and goats. It occurs rarely in adult cattle, deer, domesticated camels, and possibly horses. In pastured sheep, it causes heavy losses, particularly in flocks managed for the production of lamb and mutton. The prevalence in flocks varies a great deal but seldom exceeds 10%. The case fatality rate approximates 100%. In North America enterotoxemia ranks as one of the main causes of loss among feedlot lambs. In a survey in two feedlots the disease had an annual prevalence of 3.14% and 1.49%; it ranked third in importance as a cause of death despite a policy of vaccination, and the costs of prevention programs were the largest expenditure of all disease prevention programs in the feedlots.1

**Experimental reproduction**

The disease can be produced experimentally in susceptible sheep, goats, and cattle by the injection into the duodenum of whole culture of C. perfringens type D and dextrin or starch. Clinical disease occurs as early as 30 minutes and usually within 6–8 hours of the start of duodenal infusion and death 1–9 hours following the onset of clinical signs.2 4 The disease has also been reproduced by intravenous infusion of epsilon toxin.5

**Animal and management risk factors**

C. perfringens type D normally inhabits the alimentary tract of sheep and other ruminants but only in small numbers. The extent to which it occurs in the alimentary tract varies widely between flocks, although this accounts only in part for the variable prevalence. The organism does not persist for more than 1 year in the soil.

Under certain conditions, the organisms proliferate rapidly in the intestines and produce lethal quantities of epsilon toxin. In most, if not all circumstances, the affected animals are on highly nutritious diets and are in very good condition. The husbandry conditions in which the disease occurs include grazing on lush, rapidly growing pasture or young cereal crops, and heavy grain feeding in feedlots. Lambs on well-fed, heavy-milking ewes are particularly susceptible. The occurrence of the disease under these conditions has given rise to the name ‘overeating disease’.

Sheep

The highest incidence of the disease is in suckling lambs between 3 and 10 weeks of age. The risk for disease in this age group is highest when ewes are grazed on lush pastures that result in profuse lactation. The disease can occur following rain in set stocked flocks, and in flocks newly introduced to lush pastures is often manifest 5–14 days after introduction. Single lambs are more susceptible than twins. Weaned lambs up to 10 months of age are the second most susceptible age group and again the occurrence of disease is associated with highly nutritious diets.

Feeder lambs are most commonly affected soon after they are introduced into feedlots.

**Calves**

Enterotoxemia is most common between 1 and 4 months of age and the same risk factors pertain as for lambs. Veal calves are particularly at risk. Feeder cattle may develop disease shortly after introduction to the lot. It is a common belief among cattlemen and veterinarians that many unexplained sudden deaths in feeder cattle after the period of acclimatization are due to this type of enterotoxemia. However, there is no laboratory evidence to support such field observations and a controlled trial found no protective effect of vaccination.6

**Goats**

Enterotoxemia is a common disease in goats under intensive or extensive grazing systems, occurring in many countries,1 and is particularly important in countries with a large goat population.4 7 8 The peracute disease in goat kids has the same age occurrence as in lambs but less acute and chronic forms of enterotoxemia occur in adult goats. Sudden changes in diet appear to be the most common predisposing factor. Disease can occur in vaccinated goats, as vaccination is poorly protective against the enteric and chronic form of the disease in this species.9 7

Outbreaks in sheep and goats have followed the administration of phenothiazine and other anthelmintics, and a high incidence has been observed in association with heavy tapeworm infestation.

**Horses**

Type D enterotoxemia is rare in horses but it has been suspect in a group of mature horses fed concentrates during a drought period.9 C. perfringens type D can be isolated in high numbers from gastric reflux of horses with anterior enteritis.10

**PATHOGENESIS**

In the normal course of events, ingested C. perfringens type D are destroyed in large numbers in the ruminant abomasum, although some survive to reach the duodenum, where multiplication occurs and toxin is produced. Toxemia does not occur because the movement of ingesta keeps the bacterial population and toxin content down to a low level. In certain circumstances, this does not hold and multiplication of the organisms and the production of toxin proceeds to the point where toxemia occurs. One of the circumstances has been shown to be the passage of large quantities of starch granules into the duodenum when sheep overeat on grain diets or are changed suddenly from a ration consisting largely of roughage to one consisting mainly of...
grain. Other factors such as heavy milk feeding may have the same effect. A slowing of alimentary tract movement has also been thought to permit excess toxin accumulation and it may be that any factor that causes intestinal stasis will predispose to the disease. The importance of diet in the production of ruminal stasis has been discussed in diseases of the forestomachs of ruminants.

The epsilon toxin of C. perfringens type D increases the permeability of the intestinal mucosa to this and other toxins, thereby facilitating its own absorption.

A receptor for epsilon toxin has been identified on vascular endothelial cells, and the clinical signs and pathological findings can be explained by the widespread vascular damage and increase in vascular permeability.

Acute cases are characterized by the development in the brain of degeneration of vascular endothelium, perivascular and intercellular edema, and microscopic foci of necrosis in the basal ganglia, thalamus, internal capsule, substantia nigra, subcortical white matter, and cerebellum. The damage to the vascular endothelium leads to the accumulation of protein-rich fluid effusions observable in heart, brain, and lung. The postmortem autolysis of kidney tissue that occurs so rapidly and is the characteristic of ‘pulpy kidney’ has the same basis.

There is a pronounced hyperglycemia due to the mobilization of hepatic glycogen, severe hemococoncentration and elevation of blood concentrations of pyruvate, lactate, and alpha-ketoglutarate.

In contrast to sheep, goats with enterotoxemia produced by C. perfringens type D also have a hemorrhagic enterocolitis that is present in both the natural and the experimental disease. Peracute cases are found dead without having shown premonitory signs of illness and without evidence of struggling. The more common, acute cases show a sudden onset of bellowing, mania, and convulsions, the convulsions persisting until death occurs 1-2 hours later. Subacute cases, many of which recover, do not drink, are quiet and docile, and appear to be blind, although the eye’s preservation reflex persists. They may continue in this state for 2-3 days and then recover quickly and completely. In an outbreak of the disease in calves all three forms of the disease may be seen.

Goats
Diarrhea is a prominent sign in affected goats, especially in those that survive for more than a few days. In the peracute form, which occurs most frequently in young kids, there are convulsions after an initial attack of fever (40.5°C, 105°F) with severe abdominal pain and dysentery; death occurs in 4-36 hours. In the acute form, which is more common in adults, there is usually no fever, and abdominal pain and diarrhea are prominent with death or recovery within 2-4 days. In chronic cases, the goats may be ill for several weeks and show anorexia, intermittent severe diarrhea and, in some cases, dysentery and the presence of epithelial shreds in the feces. Chronic wasting, anemia, and eventual emaciation also occur with chronic disease in goats.

CLINICAL FINDINGS
Lambs
The course of the illness is very short, often less than 2 hours and never more than 12 hours. Many lambs are found dead without previously manifesting signs. In closely observed flocks the first signs may be dullness, depression, yawning, facial movements and loss of interest in feed. Acute cases may show little more than severe clonic convulsions with frothing at the mouth and rapid death. Cases that survive for a few hours show a green, pasty diarrhea, staggering, recumbency, opisthotonus, and severe clonic convulsions. The temperature is usually normal but may be elevated if convulsions are severe. Death occurs during a convulsion or after a short period of coma.

Adult sheep
These usually survive for longer periods, up to 24 hours. They lag behind the flock and show staggering and knuckling, champing of the jaws, salivation, and rapid, shallow, irregular respiration. There may be bloat in the terminal stages. Irritation signs, including convulsions, muscle tremor, grinding of the teeth, and salivation, may occur but are less common than in lambs.

Calves
The syndrome is similar to that seen in adult sheep, with nervous signs predominating. Peracute cases are found dead without having shown premonitory signs of illness and with no evidence of struggling. The more common, acute cases show a sudden onset of bellowing, mania, and convulsions, the convulsions persisting until death occurs 1-2 hours later. Subacute cases, many of which recover, do not drink, are quiet and docile, and appear to be blind, although the eye’s preservation reflex persists. They may continue in this state for 2-3 days and then recover quickly and completely. In an outbreak of the disease in calves all three forms of the disease may be seen.

CLINICAL PATHOLOGY
A high blood sugar level of 150-200 mmol/L and marked glycosuria are characteristic of the terminal stages of enterotoxemia in sheep, and are supportive for a diagnosis but are not pathognomonic. Hyperglycemia and glycosuria are variably present in goats with the disease.

NECROPSY FINDINGS
The body condition of the animal is usually good but there is often fecal staining of the perineum and rapid decomposition of the carcass. In peracute cases there may be no gross lesions. More frequently, there is an excess of clear, straw-colored pericardial and thoracic fluid that clots on exposure to air. Many petechiae are present in the epicardium and endocardium and there is pulmonary edema. Patchy congestion of the abomasal and intestinal mucosa is usual and the small intestine often contains a moderate amount of thin, creamy ingesta. The content of the large intestine may be watery and dark green.

The characteristic finding of soft, pulpy kidneys is only useful in animals necropsied within a few hours after death, as it is nonspecific and merely correlates to a more rapid rate of autolysis. Microscopy of experimentally induced ovine type D enterotoxemia cases confirms that the renal changes represent autolysis and not a true nephrosis.

The liver is dark and congested. The rumen and abomasum of feedlot lambs may be overloaded with concentrates. In goats there is acute fibrinonecrotic and hemorrhagic enterocolitis, although microscopic examination may be needed to detect this change.

In sheep that have not died acutely there may be symmetrical areas of hemorrhage, edema, and liquefaction in the brain, especially in the area of the basal nuclei. Again, microscopic evaluation of the tissue is critical.

Gram-stained smears of ingesta from several levels in the small intestine should be examined. In affected animals the short, fat, Gram-positive rods dominate the slide to the almost complete exclusion of other bacteria. Bowel filtrates can be tested for toxicity by injection into mice. If the filtrate is toxic, the type of toxin can be determined by protection of the mice with specific antisera, but this does not determine the type of clostridia. The detection of beta toxin indicates the presence of types B or D, and epsilon toxin the presence of B or D.

The time taken for diagnosis by mouse neutralization tests, as well as humanitarian considerations, have promoted the development of alternative tests. The RPLA test has already been discussed (see C. perfringens types B, C, and E). An ELISA test shows good specificity and sensitivity for epsilon toxin and counter-immunoelectrophoresis has an advantage of speed and requires minimal amounts of intestinal content. A recent study showed that a polyclonal capture ELISA could detect lower concentrations of epsilon toxin in intestinal fluid, pericardial...
In general, the clinical course of the disease is too acute for effective treatment. **Hyperimmune serum**, an efficient short-term prophylactic, is unlikely to be of much value in sick animals because of the acute nature of the disease. In goats the course is longer, and antitoxin in combination with orally administered sulfa dimidine may be effective in treatment. 

**CONTROL**

There are three major control measures available: reduction of the food intake, administration of antitoxin, and vaccination. These may be used individually or in combination.

**Reduction in food intake**

Reduction in food intake is the cheapest but least effective in control and is used as a short-term control while waiting for immunity to develop after vaccination. Reduction in food intake will cause a setback in the growth of the lambs and for this reason farmers tend to rely more on vaccination as a control measure.

**Antitoxin**

Antitoxin can be administered to all sheep as soon as an outbreak commences. The administration of epsilon antitoxin 200 IU/kg BW will provide for protective circulating antitoxin levels for 21–29 days. Immediate losses are prevented, and in most instances the disease does not recur. Toxoid is cheaper, but to administer it alone at such times may result in further serious losses before active immunity develops.

**Vaccination**

Immunity in sheep is readily produced by suitable vaccination. A blood level of 0.15* Welcome unit of epsilon antitoxin per milliliter of serum is sufficient to protect sheep. Vaccines available are toxoids, and adjuvants generally improve the antigenicity. Activated alum-p precipitated toxoid is the common vaccine in use.

Vaccination of maiden ewes twice at an interval of at least 1 month and with the last vaccination approximately 4 weeks before lambing will result in good passive immunity in young lambs, with 97% of lambs having protective antibody levels at 8 weeks of age and a significant proportion at 12–16 weeks of age. This is sufficient to protect lambs during their highest risk period. Older ewes that have been vaccinated the previous year receive a single booster vaccination 4 weeks before lambing. Sheep vaccinated for 3 consecutive years can be considered to be permanently immune and to require no further vaccination.

When faced with an outbreak in lambs the recommended procedure is to administer antiserum and toxoid immediately and repeat the toxoid in a month’s time. The simultaneous administration of hyperimmune serum with this vaccine does not interfere with the stimulation of antibody production, nor does the presence of passively derived colostral immunity.

Lambs can be vaccinated with toxoid when 4–10 weeks of age and again a month later.

Any vaccination of sheep is not without risk of precipitating blackleg or other clostridial disease, and if these are a serious problem in an area it may be wise to vaccinate a portion of the flock as a pilot test and proceed with vaccination of the remainder only when no complications arise. A multivalent bacterin-toxoid containing antigens to all of the clostridial diseases is commonly used in sheep in these circumstances or where all of these diseases are likely to occur. Vaccination should not be done in sheep with wet fleeces.

Vaccination with toxoid is effective in calves but is not highly effective in goats, having a limited effect in preventing the disease although reducing its incidence and severity. The anti-epider mal titer in goats following vaccination is variable and has been found equivalent to that obtained by sheep or lower and of shorter duration; however, this antibody provides minimal protection against the enterocolitis that occurs with type D infections in goats. Vaccination with current commercial vaccines has limited protective value in goats, and owners should be advised of this. The use of serum must be carried out with caution in goats, particularly Saanens, which are very prone to anaphylactic reactions. Despite the limitations of protection against the enteric manifestations of the disease, vaccination is protective against the paraeptic form of the disease and kids should be vaccinated twice, a month apart, commencing at 4 weeks of age. Subsequent vaccinations are at 6-month intervals.

Local reactions to vaccination are common in both sheep and goats and may be visible for at least 6 months. In sheep these are generally hidden by the wool but the vaccination site should be high on the neck and close to the base of the ear in order to minimize carcass blemish. With goats, especially show goats, the owner should be warned of this occurrence. Goats, especially show goats, should be vaccinated under the loose skin of the axilla where local reactions will be hidden by the elbow.

**REVIEW LITERATURE**

Nilo L. Enteroxotoxic Clostridium perfringens. In: Gyles CL, Thoen CO, eds. Pathogenesis of

REFERENCES

FOCAL SYMMETRICAL ENCEPHALOMALACIA

ETIOLOGY
The disease is a chronic neurological manifestation of enterotoxemia associated with Clostridium perfringens type D epsiloid, with vascular damage and damage to the nervous system.

EPIDEMIOLOGY
Sporadic disease in weaners and mature sheep, usually following a change of pasture or anthelmintic treatment.

CLINICAL FINDINGS
Aimless wandering, an inability to eat and a dumpy syndrome are predominant findings.

CLINICAL PATHOLOGY
None reported.

NECROPSY FINDINGS
Lesions are confined to the brain and formalin-fixed samples of this tissue may be required for confirmation of the diagnosis. In many cases the characteristic lesions can be detected on macroscopic examination and consist of areas of hemorrhage and softening in the internal capsule, lateral thalamus, and cerebellar peduncles. Malacia, edema, and hemorrhage are visible histologically. Glosysis is not a feature and toxin cannot be demonstrated in gut contents.

TREATMENT AND CONTROL
There is no treatment. Less severely affected cases may recover if they are maintained with fluids and nutrients given by stomach tube. Outbreaks cease if the sheep are vaccinated with pulpy kidney vaccine.

REFERENCES

ENTEROCOLITIS ASSOCIATED WITH CLOSTRIDIUM DIFFICILE

ETIOLOGY
Toxigenic strains of Clostridium difficile. Common bacterial etiology in antibiotic-associated diarrhea.

EPIDEMIOLOGY
Horses: most common in young foals but also occurs in adults. Commonly precipitated by therapy with antimicrobial agents. Pigs: diarrhea and mortality in pigs in first week of life.

CLINICAL FINDINGS
Diarrhea, tachypnea, dehydration, metabolic acidosis. High case fatality especially in very young foals.

NECROPSY FINDINGS
Fibrous to necrotic enterocolitis. Edema of mesocolon in pigs.

DIAGNOSTIC CONFIRMATION
Demonstration of organism and toxins.

TREATMENT
Fluids and electrolytes.

ETIOLOGY
Clostridium difficile is a recognized cause of antibiotic-associated diarrhea and pseudomembranous colitis in humans suffering perturbation of the bowel flora from antibiotic therapy or other causes. There is developing evidence that, in foals and adult horses, C. difficile can be associated with diarrheal disease that can vary from mild and self-limiting to an acute and fatal enterocolitis. Evidence for this association is the biological plausibility, some evidence that this syndrome can be reproduced experimentally, and the ability to demonstrate the organism in its toxins in the feces of horses with the enterocolitis in comparison with the low prevalence of the organism, and the absence of toxin, in the feces of nondiarrheic horses.

Commonly this syndrome occurs in horses following antimicrobial therapy and/or hospitalization. It is possible that enterotoxin from intestinal C. perfringens may also contribute in horses, and the syndrome has been called equine clostridiosis.

C. difficile is associated with diarrhea in neonatal pigs and its occurrence, or recognition, appears to be increasing.

EPIDEMIOLOGY
Occurrence
Horses
The disease is sporadic and appears to occur worldwide. In young foals within the first 2 weeks of life it may occur without apparent predisposing causes but...
in adult horses it commonly follows the use of antimicrobial agents. Case fatality rates are highest in very young foals, where the disease may also be complicated by other existing neonatal disease problems. In foals, disease may be acute, presenting with rapid recumbency and death within 24 hours of onset despite therapy, or it may present as a nonacute syndrome manifest primarily with diarrhea.

**Pigs**
The disease has increasing reportage, or recognition, and occurs predominantly in young piglets, but also is recorded as a major cause of disease and mortality in sows. The disease in piglets occurs predominantly in the first week of life, when the majority of the litter can be affected and the case fatality can approach 50% but is usually lower. Stunting is a common sequel. Outbreaks occur with or without a history of processing with antibiotics.

**Experimental reproduction**
The disease has not been effectively reproduced with simple challenge of conventional animals, suggesting that *C. difficile* in itself is not a sufficient cause.

Challenge of adult horses with *C. difficile* with and without pretreatment with penicillin did not result in clinical disease in any of the horses, but *C. difficile* was subsequently isolated at greater frequency from the feces of the horses pretreated with penicillin. Challenge of newborn foals with *C. difficile* has resulted in enteric disease and diarrhea, but only in foals not receiving adequate transfer of colostral antibodies. The disease has been reproduced in gnotobiotic but not conventional pigs.

**Risk factors**

**Animal risk factors** *C. difficile* has been isolated from the feces of 29% of 56 healthy foals less than 2 weeks of age but is not normally present, and its toxins are not commonly demonstrable in the feces of healthy horses over 1 month of age. Treatment with antimicrobials increases the likelihood of isolation from feces and occasionally the presence of toxin. In an extensive study in Sweden the feces of horses of varying age and clinical status were tested for the presence of *C. difficile* and positivity to the cytotoxin B test. The feces of 273 adult horses with no signs of enteric disease were negative to both tests; 42% of 43 horses with acute colitis treated with antibiotics were positive to one or both tests; 6% of 72 horses with colitis but no antibiotic treatment were positive to one or both tests; 2% of 47 horses with no enteric disease but treated with antibiotics were positive to both tests and none of 65 horses with colic were positive.

**Environmental risk factors** Treatment with antimicrobials is a risk factor for the occurrence of *C. difficile* in the feces of both normal foals and normal adult horses. Antimicrobial therapy is also a risk factor for the occurrence of *C. difficile*-associated enterocolitis. Treatment with penicillin is a major risk factor but the specific incrimination of penicillin may simply reflect its common use as an antimicrobial in horses. There is a risk for mares to develop acute enteritis associated with *C. difficile* when their foals are being treated for *R. equi* pneumonia with erythromycin and rifampicin. It was suspected that the risk occurred as a result of the mares' exposure to these antibiotics from the foal feces or contaminated materials in the environment.

Routine prophylactic antimicrobial treatment of periparturient sows for diseases such as mastitis-metritis-agalactia have resulted in outbreaks of enterocolitis.

**Pathogen risk factors**

Pathogenic strains of *C. difficile* produce an enterotoxin (toxin A) and a cytotoxin (toxin B). There are degrees of virulence between strains but nontoxigenic strains are considered nonpathogenic. Other virulence factors, including an actin-specific adenosine diphosphate (ADP)-ribosylating toxin and an outer cell surface coat S-layer, have been proposed as additional virulence factors.

The organism can be isolated from a number of environmental samples, including soil and the environment of veterinary hospitals. Although it appears that the organism is not commonly present in the feces of normal horses, it can be isolated from those of other animal species and has high prevalence in the feces of dogs and cats. The organism can survive in feces for at least 4 years. Spores are resistant to common disinfectants but a 5% bleach solution is stated to be effective for disinfection.

**Zoonotic implications**

*C. difficile* is a cause of diarrhea in humans and most commonly occurs following the administration of antibiotics, although sporadic cases without these risk factors also occur. The disease in humans may be mild and self-limiting or develop to severe pseudomembranous colitis with risk of intestinal perforation. In one study using molecular typing, 25% of isolates from humans were indistinguishable from isolates from animals. The risk for zoonotic infection should be considered but barrier protection and attention to personal hygiene when handling animal cases should limit the risk for infection. Veterinarians and animal handlers undergoing antimicrobial therapy are particularly at risk.

**PATHOGENESIS**

The disease is associated with severe watery diarrhea and a hemorrhagic necrotizing enterocolitis. The enterotoxin A damages villous tip and brush border membranes and causes necrosis and increased intestinal permeability. The cytotoxin B is lethal to cells once the gut wall has been damaged. Complete erosion of the mucosa may result. Both toxins induce the production of tumor necrosis factor and proinflammatory interleukins, with a resultant inflammatory response and pseudomembrane formation. Lactose intolerance may develop secondary to infection.

**CLINICAL FINDINGS**

**Horses**

Disease occurring with onset in the first 2 weeks of life is initially manifest with a decreased interest in sucking, often with signs of colic with increasingly prolonged and severe episodes of rolling and kicking at the abdomen and the occurrence of profound dehydration and occasionally hemorrhagic diarrhea. Rectal temperatures are within the normal range but there is severe dehydration, an elevation of heart rate and respiratory rate, acidemia attributable to metabolic acidosis, and the development of septic shock. There is progressive enlargement of the abdomen, and transcutaneous ultrasound shows thickened, fluid-filled loops of intestine and fluid in the ventral abdomen.

In adult horses the disease is manifest with acute and often fatal colitis with profuse diarrhea, toxemia, hypovolemia, and metabolic acidosis, and is reported in individuals and as outbreaks in horses hospitalized and treated for various diseases.

**Pigs**

Affected piglets are depressed and have a yellow, mucoid diarrhea with occasional piglets passing feces with specks of blood. As the condition progresses, affected pigs show abdominal distension and tachypnea, and some have scrotal edema. There is progressive dehydration and hypoglycemia.

**CLINICAL PATHOLOGY**

There is a leukopenia, a toxic left shift, a high hematocrit, and hyperfibrinogenemia. Plasma protein may be normal to low and there are a high bilirubin and elevated liver enzyme values. Metabolic acidosis, as evidenced by an increase in anion gap and decrease in total CO₂ concentration, hyponatremia and azotemia are present. Blood IgG concentrations are commonly within the normal range.
Classic methods of diagnosis are by examination of feces by culture of the organism and demonstration of toxins A and B by cytotoxin assays and enzyme immunoassays. Cycloserine-cefoxitin-fructose agar is commonly used to isolate *C. difficile* from feces. The isolation of *C. difficile*, in itself, is generally not considered to be diagnostic and should be accompanied by demonstration of toxin A in the feces by ELISA, or by tissue culture cytotoxin assays, to allow a putative diagnosis. Fecal toxin testing in live animals is an effective method of diagnostic confirmation and correlates highly with toxin tests on intestinal contents at postmortem.

The organism, but not the toxins, is labile when kept aerobically at 4°C, with a significant decrease in recovery after 24 hours. Consequently, samples for culture should be taken in anaerobic transport media and shipped on ice.

ELISA tests may lack sensitivity and only detect toxin A whereas some pathogenic strains produce only toxin B. Consequently PCR may provide a more reliable method of detection. Feces, or isolates, can be tested for genes encoding toxins A and B by PCR and PCR can also be used retrospectively following postmortem for diagnosis in formalin-fixed tissues.

**NECROPSY FINDINGS**

**Horses**  
Gross findings are of enterocolitis with histological findings that vary from a superficial fibrinous colitis with hemorrhage and edema to a severe hemorrhagic multifocal necrosuppurative and ulcerative enterocolitis.

**Pigs**  
The contents of the small intestine are scant and those of the large intestine yellow to dark yellow in color. Edema of the mesocolon is a common finding, along with increased fluid in the peritoneal and pleural cavities. Histological findings vary from necrosis and exfoliation of the intestinal mucosa to segmental transmural necrosis in the large intestine. C. difficile

**DIFFERENTIAL DIAGNOSIS**

- **Horses** – See Table 5.13
- **Swine** – See Table 5.14

**TREATMENT**

Horses should be aggressively treated with fluids, plasma, and pressors, to correct the fluid and electrolyte imbalance, correct the metabolic acidosis and control pain. Antimicrobial therapy should be based on sensitivity. Isolates are usually resistant to trimethoprim-sulfamethoxazole and bacitracin, variably resistant to rifampicin and susceptible to vancomycin. Metronidazole, 10 mg/kg intravenously four times daily or 15 mg/kg orally four times daily, has been commonly used for therapy but there is geographical variation in sensitivity. Metronidazole and vancomycin are not approved for use in food animal species in most countries.

In vitro studies have shown that di-tri-octahedral (DTO) smectite can bind *C. difficile* toxins A and B and that this can occur without inhibiting the antibacterial action of metronidazole. Clinical trials of efficacy have not been conducted but pharmacological considerations indicate that an initial dose of 1.4 kg of DTO smectite, administered by stomach tube, followed by 454 g every 6–8 hours could be of therapeutic value. Experimental studies in hamsters indicate promise for the use of immune sera and vaccines, but these are not currently available in agricultural animals.

**CONTROL**

There is no definitive control procedure. The organism is commonly present in veterinary environments and equine environments where there are foals. Foaling areas should be clean and disinfected with a sporidical disinfectant. Metronidazole, 500 mg administered orally twice a day for 2 weeks, may be indicated for at-risk horses. Clinical cases should be isolated and, in a veterinary environment, strict barrier protection established between them and other animals under antimicrobial therapy. Orally administered probiotics and lactic-acid-producing bacteria are in use as an aid to prevention but there are no data on efficacy.

Diseases associated with *Escherichia coli*

Colibacillosis, associated with *Escherichia coli*, occurs in all species of newborn farm animals and is a major cause of economic loss in this age group. Gut edema and enteric colibacillosis of recently weaned pigs are also important diseases associated with this organism.

*E. coli* is a major cause of diarrhea in calves, piglets, and lambs, and the term ‘colibacillosis’ is commonly used; however, diarrhea in newborn calves, for example (and in other species too), can be associated with several different enteropathogens influenced by several risk factors (Table 18.1). Colibacillosis is presented in this chapter. Information on the viral diarrheas of newborn farm animals is presented in Chapter 21. Diarrhea associated with *Cryptosporidium* is presented in Chapter 26. This section first outlines the general aspects of acute undifferentiated diarrhea of newborn farm animals, with emphasis on the disease in calves. Many of the principles can be applied to the other species. This is followed by the diseases associated with *E. coli*.

ACUTE UNDIFFERENTIATED DIARRHEA OF NEWBORN FARM ANIMALS (PARTICULARLY CALVES AND PIGLETS)

Diarrhea in newborn farm animals, particularly calves under 30 days of age and piglets in the first week of life, is one of the most common disease complexes that the large-animal clinician encounters in practice. It is a significant cause of economic loss in cattle and pig herds and continues to assume major importance as livestock production becomes more intensified. The effective treatment and control of herd epidemics of diarrhea in calves and piglets can be frustrating and unreliable. Considerable progress has been made in the treatment of the effects of diarrhea such as dehydration and acidosis but less so in the control of these disease complexes.

The causes of calf and piglet diarrhea are complex and usually involve an
interaction between enteropathogenic bacteria, viruses, and protozoa, the colostral immunity of the animal and the effects of the environment (Tables 18.1–18.3). Thus the term acute undifferentiated diarrhea of newborn calves is used to describe the acute diarrhea that occurs in newborn calves under 30 days of age, characterized clinically by acute profuse watery diarrhea, progressive dehydration and acidosis and death in a few days, or earlier after onset if treatment is not provided. Based on clinical findings alone, it is not usually possible to differentiate between the common known causes of diarrhea in newborn calves, which include enterotoxigenic *E. coli* (ETEC), verocytoxic *E. coli* (VTB), necrotogenic *E. coli* (NTEC), rotavirus, coronavirus, bovine torovirus (Breda virus), calicivirus, norovirus (Norwalk-like virus), *Cryptosporidium* spp., *Giardia* spp., and *Salmonella* spp. The common necropsy findings are dehydration, emaciation, and a fluid-filled intestinal tract, with no other obvious gross lesions. The exceptions are enteritis associated with *Salmonella* spp., *Clostridium perfringens* types B and C, *Eimeria* spp., and attaching and effacing *E. coli*, in which there are usually typical gross lesions at necropsy.

Thus the disease is considered to be a complex syndrome because one or any combination of more than one of the specific etiological agents may be the cause of the disease. Risk factors may also precipitate the disease in calves in which the disease might not normally occur, even though they are infected with a specific enteropathogen. The term acute undifferentiated diarrhea of newborn calves is useful to encompass cases of undifferentiated diarrhea of newborn calves is useful to encompass cases of undifferentiated diarrhea of newborn calves, which may include a combination of more than one of the specific etiological agents.

**RISK FACTORS**

A risk factor is any circumstance that can contribute to the occurrence of the disease. Conversely, if that circumstance is not present the disease may not occur. Many interrelated risk factors have been associated with a high incidence of calf diarrhea and have added to the difficulty of understanding the complexity of the disease and controlling it. The identification and modification or removal of these risk factors can be very effective in the clinical management and control of epidemics of the disease.

**Animal risk factors**

The host risk factors include immaturity of the neonate at birth, age of the neonate, a lack of vigor of the calf or piglet at birth, the presence of intrapartum hypoxemia and acidosis from a difficult birth, and failure to acquire sufficient colostral immunity. The nutrition of the pregnant dam can affect the quantity and quality of colostrum, and consequently the vigor of the calf.

**Colostral immunoglobulin status**

The role of colostrum in protecting the newborn calf from the effects of enteropathogens is well known. The failure of the newborn calf to ingest an adequate quantity of good-quality colostrum containing a high level of colostral immunoglobulins within a few hours after birth is a major risk factor contributing to acute undifferentiated diarrhea. Complete or partial failure of transfer of passive immunity is highly prevalent in diarrheal veal calves infected with cryptosporidia, coronavirus, and rotavirus. Early work centered on the protective effect of colostrum against septicemic and enteric colibacillosis. More recently, the role of colostral and milk antibodies against rotavirus and coronavirus enteritis in newborn calves has been established. Specific protection against these viral diarrheas in the newborn calf depends on the level of antibody in the lumen of the intestine. While it is easy to state that calves should receive liberal quantities of colostrum, the veterinarian in the field who encounters an outbreak of acute diarrhea in beef calves, for example, cannot usually easily determine whether in fact the calves possess protective levels of immunoglobulins.

**Lactose intolerance** as a cause of diarrhea has been reported in a calf but its occurrence is rare.

Cases of diarrhea due to specific nutritional deficiencies are reported rarely and not well documented. However, field observations indicate that outbreaks of diarrhea in suckling beef calves may have been associated with specific nutrient deficiencies such as copper or selenium. These are not documented but should be considered in certain situations where these deficiencies are known to be present in the herd. An epidemic of intractable diarrhea in 2-month-old beef calves was associated with deficient tissue and plasma levels of vitamin E in the affected calves, which also had lesions of skeletal and myocardial muscular dystrophy with adequate levels of selenium. A combination of low vitamin E status and low immunoglobulin status may be a contributing factor in neonatal diarrhea of calves, but this is not well documented.

Environmental and management risk factors

Veterinarians have commonly observed a relationship between adverse climatic conditions and epidemics of diarrhea in calves. During inclement weather, such as a snowstorm, a common practice in beef herds is to confine the calves in a small area where they can be fed and watered, and observed, more easily. The overcrowding may be followed by an outbreak of calf diarrhea. Cold, wet, windy weather during the winter months in temperate climates and hot humid weather during the summer months may be associated with an increased incidence of dairy calf mortality due to diarrhea. Changes in weather and wet, windy and cold weather are commonly associated with subsequent outbreaks of the disease in beef calves raised outdoors. Increases in population density in calf houses, and on calving grounds, resulting in highly contaminated calving grounds, are important risk factors. In beef herds in the USA and Canada, the risk factors that are associated with an increase in calf mortality from diarrhea include:

- The herd of origin. This is because of the genetic composition of the cattle, environmental conditions, degree of exposure to pathogens and management practices unique to the herd.
- Increasing the percentage of heifers calving in the herd. The risk of diarrhea in calves born to heifers may be about four times greater than in calves born to cows.
- The odds of diarrhea occurring in calves born on or after the median calving date is twice that of calves born before the median calving date. This may be because of increased pathogen exposure as the calving season progresses.
- Poor drainage and limited shelter in the nursery yards.
- A decrease in the size of the effective calving yards because of poor drainage and wetness.
- Wintering and calving cows and heifers on the same grounds.

Some studies have shown that the major contributing factor to dairy calf mortality is the care provided by the calf attendant. Not infrequently, however, outbreaks can occur in herds in which the management is excellent and not uncommonly an etiological diagnosis cannot be made.

Certain herd characteristics and herd management practices are associated with an increased incidence of diarrhea in dairy herds. Larger herd size is associated with an increased incidence of diarrhea. The greater disease rate may be associated with a greater possibility of a large epidemic in a larger population, and cows in larger herds may be more densely housed. In dairy herds with 10–49 cows, the number of young stock at the end of the month, the incidence density of...
respiratory disease in the calves per herd per calf-month, and the cumulative incidence of vaccinations for calves given to prevent diarrhea may be associated with increased incidence of diarrhea. As the incidence of respiratory disease increases in large dairy herds, the incidence of diarrhea in the calves increases, especially in large herds of over 200 cows. Reduction of the incidence of respiratory disease in calves will result in a decrease in the incidence of diarrheal disease. The use of individual maternity stalls and regular removal of bedding between calvings is associated with a decrease in the incidence of neonatal calf diarrhea. As the number of calves in the herd increases, calf attendants may become too busy to perform duties of calf care thoroughly. Overcrowding may also be a risk factor.

Dairy calves fed milk replacers may develop diarrhea because of the inferior quality of some milk replacers.

Epidemics of diarrhea in piglets are commonly associated with inadequate sanitation and hygiene in the farrowing rooms, which may be under continuous use without sufficient time for cleaning and disinfection between farrowings. Certain management procedures may be associated with differences in the prevalence of enteropathogens.

In dairy calves fed on nipple feeders there may be increased probability of the calves shedding detectable fecal levels of *Salmonella*, *E. coli*, rotavirus, or coronavirus. The use of group pens has been associated with increased odds of encountering *Campylobacter jejuni*, the presence of which is of uncertain significance. Calves with diarrhea on these farms tend to have increased odds of shedding rotavirus and *K99" E. coli*.

**Pathogen risk factors**

Calves

The distribution and occurrence of enteropathogens in the feces of diarrheic and normal healthy calves varies depending on the geographical location, the farm, the age and type of calves being examined, and the extent to which the diagnostic laboratory is capable of isolating or demonstrating the pathogens. Rotavirus, *Cryptosporidium* spp., coronavirus, and enterotoxigenic *E. coli*, collectively, are responsible for 75–95% of infections in neonatal calves worldwide. The relative frequencies of each of the four differ between locations and between seasons and years. Any one of the common pathogens may predominate or be absent in a certain group of animals. Mixed infections are common. Rotavirus will be most common in some groups, especially housed calves. Coronaviruses may predominate in beef calves in some countries and not in others, and *Cryptosporidium* may occur in 30–50% of diarrheic calves on a worldwide basis. A survey of veal calf farms revealed that *Cryptosporidium* infection is an important cause of transient diarrhea and that there was no association between diarrhea and infection with either *Salmonella* spp., enterotoxigenic *E. coli*, rotavirus, or verotoxigenic *E. coli* in the population examined. Cryptosporidia, rotavirus, and coronavirus are the most commonly identified enteropathogens in intensively reared veal calves. In dairy calves, the prevalences of giardiasis and *Cryptosporidium* may be high and both parasites may be associated with diarrhea. *Cryptosporidium parvum* is an important pathogen in calves under 1 month of age, but *Giardia duodenalis* may be more important when calves are older. Calves may clear *C. parvum* infections within 2 weeks; however, *G. duodenalis* infections may become chronic in the same calves. The combination of *Cryptosporidium* sp. and rotavirus may predominate in some situations. *Cryptosporidium* spp. were the second most commonly detected pathogens next to rotavirus, and case-control studies indicated a highly significant association with diarrhea. Enteropathogens may not be detectable in up to 30% of diarrheic calves. *Eimeria* spp. can cause coccidiosis in calves any time after about 21 days after birth but the disease is more common in calves several months old. In some countries, enterotoxigenic K99" *E. coli* may occur in 30–40% of diarrheic calves, while in others the incidence may be as low as 3–6%. Attaching and effacing *E. coli* that cause hemorrhagic colitis and blood in the feces of diarrheic calves about 2 weeks of age are being recognized with increasing frequency. They may occur concurrently with other enteropathogens (cryptosporidia, rotavirus, coronavirus, enterotoxigenic *E. coli*, bovine virus diarrhea virus (BVDV), and coccidiosis). Some isolates of attaching and effacing *E. coli* produce verocytotoxin.

The age occurrence of the common enteropathogens associated with diarrhea in calves is shown in Table 18.2. Case-control studies of diarrheic and healthy calves from the same groups indicate that the enteropathogens commonly found in diarrheic calves are more prevalent in healthy calves than in herds free from major enteric pathogens. Campylobacter spp. and *Yersinia* spp. are well adapted to the bovine host and can be found in the feces of diarrheic and healthy calves at a similar prevalence. Their significance as pathogens in newborn calves is questionable. They are probably part of the normal enteric flora of ruminants. However, as they represent a source of gastrointestinal infections in humans, management factors limiting intestinal colonization of these bacteria should be considered in beef cow/calf herds.

Rotavirus and coronavirus occur with almost equal frequency in the intestinal tracts of normal and diarrheic calves of some studies. Intestinal lesions compatible with the viral infections are found in about 70% of diarrheic calves. Thus, these viruses are widespread in the bovine population and only under some circumstances will the infection be severe enough to cause lesions and diarrhea. Other viruses, such as parvovirus, astrovirus, Breda virus, and calici-like virus, have been isolated from the feces of diarrheic calves but their role in the etiology is yet to be defined.

A necrotizing enteritis of suckled beef calves 7–10 weeks of age on pasture in Scotland has been reported. Fever, acute diarrhea and dysentery, and a case fatality rate of 25% are characteristic. No etiological agent has been identified.

Lambs and goat kids

The *E. coli* strains isolated from diarrheic lambs and goat kids on Spanish farms are not generally toxigenic and belong to a large number of O serogroups.
enteropathogens that are commonly present in the feces include the transmissible gastroenteritis (TGE) virus, enterotoxigenic E. coli, Isospora spp., rotavirus, C. perfringens type C, and adenovirus. Clotridium difficile has emerged as an important pathogen causing enteritis in suckling piglets. The TGE virus causes diarrhea in piglets under 15 days of age, enterotoxigenic E. coli under 5 days of age, Isospora sp. between 5 and 15 days of age, and rotavirus in piglets over 10 days of age. During the second and third weeks of life, Isospora suis is the most common pathogen in outbreaks of diarrhea in litters of piglets. While individual piglets may be infected by a single pathogen, it is common for more than one pathogen to be present in the litter. This stresses the importance of submitting to the diagnostic laboratory some piglets that are representative of the problem. A seasonal occurrence of the common enteropathogens has also been observed. The prevalence of the TGE virus may be highest during the fall, winter, and spring months, and the coccidia and E. coli are more common during the summer, fall, and early winter, with the lowest prevalence in the spring.

Foals
Diarrhea in foals is common but most cases are mild, transient and not associated with infectious agents. Diarrhea is the most commonly reported disease in foals under 7 days of age. The most common occurrence is associated with foal heat in the mare. Group A rotavirus is the most common cause of epidemics of diarrhea in foals. Enterotoxigenic E. coli has been isolated from a diarrheic foal. Other pathogens that have been isolated from foals with diarrhea include C. jejuni, C. perfringens, and Rhodococcus equi.

CLINICAL MANAGEMENT OF EPIDEMICS
When faced with an outbreak of acute diarrhea in newborn calves in which there is profuse watery diarrhea, progressive dehydration, and death in a few days or earlier, the following steps are recommended:

1. Visit the herd and do an epidemiological investigation to identify the risk factors that may have been responsible for the outbreak. Most outbreaks are multifactorial and an interaction between the environment, management, feeding and the pathogens. The investigation of the underlying causes of the outbreak should involve an examination of:
   - Dry cow management
   - Calving management
   - Colostrum management

   - Calf management
   - Calf feeding
   - Feeds used
   - History of the present outbreak
   - The affected calves
   - Results of necropsy and pathology and microbiology
   - The pathogens identified
   - What has changed in the management of the herd

2. Each of the commonly recognized risk factors must be examined for its possible role in the particular outbreak:
   - In beef herds the most common one is overcrowding in the calving yards, which results in increased contamination and a high infection rate
   - Recent changes in climate and recent stress of any kind on the herd are common
   - In dairy herds, the quality of the milk replacer should be investigated
   - Any recent introductions of replacement calves into the herd should be considered as possible sources of pathogens
   - The failure of calves to ingest an adequate quantity of colostrum within hours after birth is also an important risk factor. However, it is usually not possible to determine how much colostrum calves have ingested, and measurement of serum immunoglobulins of calves about 3 days of age may be necessary to determine the level of colostral immunity in the calf crop. The concentrations of total serum protein and serum gammaglobulin are usually lower in calves with diarrhea, and calves born between May and October have higher levels than calves born in April

3. Affected calves should be examined clinically, dead ones by necropsy, and a case definition should be determined to insure that diarrhea is the major problem

4. All affected calves should be identified, isolated and treated immediately with oral and parenteral fluid therapy as indicated. The use of oral fluid and electrolyte therapy for the treatment of dehydration and acidosis as soon as the calves are seen to be diarrheic must be emphasized

5. Antibacterials may be given orally and parenterally for the treatment of enteric and septicemic colibacillosis. When large numbers of calves are affected at one time it is not usually possible clinically or with the aid of a laboratory to determine which calf is septicemic, and thus all acutely affected calves should be treated.

Treatment, however, should not be continued beyond 3 days

6. Fecal samples (30–50 g) should be collected from diarrheic calves at the first sign of diarrhea, and from normal calves, and submitted to a laboratory for the attempted isolation and characterization of enterotoxigenic E. coli, rotaviruses, and Salmonella spp. A rapid enzyme-linked immunosorbent assay (ELISA) test is available for the simultaneous detection of Escherichia coli K99 antigen, bovine coronavirus, and rotavirus in the feces of diarrheic calves during the acute phase of the infection. The Enterosure Kit is a monoclonal antibody ELISA for the detection of bovine coronavirus, rotavirus serogroup A, and K99 E. coli antigen. The Cryptosure Kit is a substantial improvement over the stain method for detecting cryptosporidia in the feces. Blood samples from affected and normal calves and colostrum samples, if available, are useful for immunoglobulin and antibody studies. All moribund calves should be submitted for necropsy before they die naturally

7. Pregnant cows that are due to calve shortly should be moved to a new calving area. In a dairy herd this means a different, clean calving stall, preferably in another barn not previously occupied by cattle; in beef herds it may mean moving a large number of cows to a new, uncontaminated calving pasture

8. The control of the disease in future calf crops will depend on application of the principles of control, which are described under colibacillosis and viral diarrhea of calves. If a significant number of cows are due to calve in more than 3–6 weeks, vaccination with the calf diarrhea vaccines can be considered

9. A report should be submitted to the owner that records the observations made at the farm visit and outlines specific recommendations for clinical management of affected calves and for control of the disease in the future.

CONTROL
The principles of control are presented in detail in the sections on colibacillosis of newborn calves, piglets, lambs, kids, and foals, and viral diarrhea in calves, lambs, kids, piglets, and foals, using the following principles:

- Reduction of the degree of exposure of the newborn to the infectious agents
• Provision of maximum nonspecific resistance with adequate colostrum and optimum animal management
• Increasing the specific resistance of the newborn by vaccination of the dam or the newborn.

**REVIEW LITERATURE**

**REFERENCES**

**COLIBACILLOSIS OF NEWBORN CALVES, PIGLETS, LAMBS, KIDS, AND FOALS**

**Synopsis**

**Etiology** Pathogenic serotypes of *Escherichia coli*: septicemic, enterotoxigenic, enteropathogenic (EPEC), enterohemorrhagic (EHEC), also referred to as verocytotoxigenic (VTEC) or Shiga-toxin-producing (STEC), and necrotogenic *E. coli* (NTEC).

**Epidemiology** Newborn calves, piglets, lambs, goat kids, foals. Risk factors include colostrum deprivation, overcrowding, adverse climatic conditions, inferior milk replacers. Prevalence of enteropathogenic *E. coli* varies between herds. Enterohemorrhagic *E. coli* (O157:H7) in cattle is of major zoonotic concern.

**Signs** Weakness and collapse (septicemia). Diarrhea. Dehydration. Complications such as meningitis.

**Clinical pathology** Isolate organism from feces. Hematology and serum biochemistry to evaluate inflammation and acid–base and electrolyte imbalance.

**Lesions** Septicemic lesions. Dehydration, enteritis.

**Diagnostic confirmation** Culture of organism and serotyping.

**Differential diagnosis** See Table 18.3. *E. coli* infections causing sepsisemia and diarrhea in newborn farm animals must be differentiated from the following:

- Septicemia in calves
- Salmonella spp.
- *Listeria monocytogenes*
- *Mannheimia haemolytica*
- *Streptococcus spp.*
- *Pneumococcus*
- Septicemia in piglets
- *Streptococcus spp.*
- *Listeria monocytogenes*
- Septicemia in lambs and kids
- *Salmonella spp.*
- *Listeria monocytogenes*
- *Erysipelothrix rhusiopathiae*
- Septicemia in foals
- *Actinobacillus equuli*
- *Salmonella abortus equi*
- *Salmonella typhimurium*
- *Streptococcus pyogenes*
- *Listeria monocytogenes*
- Acute neonatal diarrhea in calves
- *Rotavirus* and coronavirus
- *Cryptosporidium spp.*
- *Salmonella spp.*
- *Eimeria spp.*
- *Clostridium perfringens* type C
- Acute neonatal diarrhea in piglets
- *Rotavirus*
- Transmissible gastroenteritis virus
- *Clostridium perfringens* type C
- *Isospora spp.*
- Acute neonatal diarrhea in lambs and kids
- *Coronavirus*
- *Cryptosporidium spp.*
- *Clostridium perfringens* type C
- *Rotavirus*
- Acute neonatal diarrhea of foals
- *Salmonella spp.*
- *Eimeria spp.*
- Foal heat diarrhea

**Treatment** Antimicrobials. Fluid and electrolyte therapy.

**Control** Reduce infection pressure on neonate. Insure adequate intake of colostrum. Vaccinate pregnant dam to induce specific colostrum antibody. Minimize stressors and their effect on neonates.

**ETIOLOGY**

Colibacillosis is associated with pathogenic serotypes of *Escherichia coli*. The prevalence of the different pathogenic serotypes of *E. coli* in farm animals has remained relatively unchanged for many years. Certain serotypes cause diarrhea and others cause septicemia.

- Enteropathogenic *E. coli* are the ‘attaching and effacing’ strains that colonize the small intestine, where they attach tightly to the epithelial cells of the villus and cause typical attaching and effacing lesions. They do not produce toxins and seldom invade the intestinal mucosa.
- Enterohemorrhagic *E. coli* strains elaborate very potent Shiga toxins. The enterohemorrhagic *E. coli* are considered to be a subset of Shiga-toxin-producing or verotoxin-producing strains of *E. coli*. They are not an important cause of diarrhea in farm animals but some Shiga-toxin-producing *E. coli* have been responsible for diarrhea in calves. Cattle are an important reservoir of *E. coli* O157:H7, one of the important enterohemorrhagic *E. coli* strains, causing a broad range of clinical disease in humans including diarrhea and hemorrhagic colitis, and the highly fatal hemolytic-uremic syndrome in children. See ‘Enterohemorrhagic *Escherichia coli* in farm animals and zoonotic implications’, below.
- Necrotogenic *E. coli* (NTEC) strains produce cytotoxic necrotizing factor (CNF) or 2. NTEC2 isolates are restricted to calves and lambs with diarrhea and septicemia.
- Septicemic *E. coli* strains of serogroup O78 are invasive and cause septicemia in calves, piglets, and lambs. Their powerful endotoxins cause endotoxin shock with a high case fatality rate.

**EPIDEMIOLOGY**

Occurrence and prevalence of infection

The prevalence of colibacillosis has increased in recent years. There are several possible reasons for this, including size of herds, shortage of qualified labor, automated livestock rearing systems, and increased population density.

Colibacillosis occurs most commonly in newborn farm animals and is a significant cause of economic loss in raising livestock. It is a complex disease in which several different risk factors interact with certain pathogens, resulting in the disease. There are at least two different types of the disease: *enteric colibacillosis* is characterized by varying degrees of diarrhea, dehydration, acidosis, and death in a few days if not treated, *coliform septicemia* is characterized by severe illness and rapid death in several hours.

**Calves**

The prevalence of enterotoxigenic *E. coli* in diarrheic calves varies widely geographically, between herds and depending on...
the age of the animals. The prevalence can be as high as 50–60% in diarrheic calves under 3 days of age and only 5–10% in diarrheic calves 8 days of age. In some countries the prevalence is only 5–8% in diarrheic calves under 3 days of age. Thus enterotoxigenic colibacillosis is a major cause of diarrhea in calves less than 3 days of age and is not associated with outbreaks of diarrhea in calves older than 3 days. Enterotoxigenic E. coli infection in calves older than 2–3 days will in most cases be associated with a virus infection. The prevalence of the organism is also very low or not present in clinically normal calves in herds that have not had a problem with diarrhea. In some beef herds affected with diarrhea in young calves there may be little evidence of infection with enterotoxigenic E. coli, and other factors need to be examined.

**Calves**
- Bacteremia/septicemia
  - Escherichia coli
  - Salmonella spp.
  - Listeria monocytogenes
  - Pasteurella spp.
  - Streptococcus spp.
  - Pneumococcus spp.
- Acute neonatal diarrhea
  - Enteropathogenic and enterotoxigenic E. coli
  - Rotavirus
  - Coronavirus
  - Bovine torovirus (Breda virus)
  - Bovine calcivirus
  - Bovine norovirus
  - Cryptosporidium spp.
  - Giardia spp.
  - Salmonella spp.
  - Eimeria spp. (calves at least 3 weeks old)
  - Clostridium perfringens type C

**Piglets**
- Bacteremia/septicemia
  - Escherichia coli
  - Streptococcus
  - Listeria monocytogenes
- Acute neonatal diarrhea
  - Enteropathogenic and enterotoxigenic E. coli
  - Salmonella spp.
  - Transmissible gastroenteritis virus
  - Clostridium perfringens type C (rarely A)
  - Clostridium difficile
  - Rotavirus
  - PRRSV
  - Isospora spp.

**Lambs and kids**
- Acute neonatal diarrhea
  - Clostridium perfringens type C
  - C. perfringens type B (lamb dysentery)
  - Rotavirus
  - Caprine herpesvirus

**Foals**
- Acute neonatal diarrhea
  - Foal-heat diarrhea
  - Rotavirus
  - Clostridium perfringens type B

PRRSV, porcine reproductive and respiratory syndrome virus

3% in well-managed herds to a high of 60% in problem herds in certain years.

**Piglets**
In piglets the morbidity rate of preweaning diarrhea varies widely between herds but averages about 6% of litters, mostly in the first week of life. The morbidity rates increase with increased litter size and decrease with increasing parity of the sow. Losses due to stillbirths, traumatic injuries, starvation, and undersize at birth account for a much greater combined preweaning loss but colibacillosis accounts for approximately 50% of the gastroenteropathies encountered during the preweaning period.

**Foals and lambs**
Incidence rates are not readily available for foals and lambs, but E. coli is the most commonly isolated organism from the tissues and blood of septic foals.

**Risk factors**
Several risk factors influence the occurrence of the disease, each one of which must be considered, evaluated and modified or removed if necessary when investigating the cause of an outbreak so that effective clinical management and control of the disease may be achieved.

**Animal risk factors**

**Age and birth weight**
Colibacillosis is most common in animals under 3 days of age but it may occur as early as 12–18 hours after birth and occasionally occurs in calves up to several days of age when there is a mixed infection with viral enteropathogens. Diarrhea associated with enterotoxigenic E. coli occurs in calves mainly during the first few days of life, rarely in older calves and never in adults. Epidemiological studies of both beef and dairy calves indicate that more than 80% of clinical cases associated with K99 enterotoxigenic E. coli occur in calves younger than 4 days of age. The mechanism of this age-related resistance is not well understood but may be related to development of resistance to colonization of the small intestine as the calf becomes older. This could be associated with the replacement of villous epithelial cells that occurs in the first few days after birth.

Mortality due to colibacillosis is significantly higher in goat kids that are underweight at birth because of multiple births, which may result in the ingestion of inadequate amounts of colostrum.

The disease is more common in piglets born from gilts than from sows, which suggests that immunity develops with developing age in the sow and is transferred to the piglets. In a survey of approximately 4400 litters of piglets over a period of 4 years in a large piggery, 64% of the litters were treated for diarrhea before weaning, and piglets born to sows under parity 2 were 1.7 times more likely to develop diarrhea before weaning than litters born to sows over parity 3. The susceptibility or resistance to E. coli diarrhea in piglets has an inherited basis.

The cell surface receptor for the K88 antigen is inherited in a simple mendelian way with adherence (S) dominant over nonadherence (s). Homozygous dominants (SS) and heterozygotes (Ss) possess the receptor and are susceptible, whereas in the homozygous recessive (ss) the receptor is absent and the pigs are resistant. The highest incidence of diarrhea occurs in susceptible progeny born from resistant
Immunity and colostrum

Newborn farm animals are agammaglobulinemic and must ingest colostrum and absorb colostral immunoglobulins within hours of birth to obtain protection against septicemic and enteric colibacillosis. The transfer of immunoglobulins from the dam to the neonate is termed transfer of passive immunity. Failure of transfer of passive immunity predisposes the neonate to development of infectious diseases. 

Calves Transfer of maternal immunoglobulins to calves depends on three successive processes:

- Formation of colostrum with a high concentration of immunoglobulin by the dam
- Ingestion of an adequate volume of colostrum by the calf
- Efficient absorption of colostral immunoglobulins by the calf.

Colostral immunoglobulins are absorbed for up to 24 hours after birth in calves and up to 48 hours in piglets. However, in calves maximum efficiency of absorption occurs during the first 6-12 hours after birth and decreases rapidly from 12-24 hours after birth. Following absorption, transfer to the intestinal lumen is a major means of IgG clearance in calves, and this transfer results in antigen-binding antibody in the intestinal lumen. Both blood-derived antibody and lactogenic antibody are significant sources of passive antibody in the intestinal lumen of the neonatal calf. Maintenance of high concentrations of milk-derived antibodies in the small intestinal lumen may require more than twice-a-day feedings, since antibodies derived from a milk diet are predominantly cleared from the intestinal lumen by 12 hours after feeding.

Passively acquired antibody from the circulation entering the small intestinal lumen is, therefore, a reasonable hypothesis to explain the strong association between high serum passive immunoglobulin concentrations and reduced morbidity in neonatal calves.

Newborn dairy calves should ingest 80-100 g of colostral immunoglobulin Gs, and ideally up to 150 g, within a few hours after birth in order to achieve serum immunoglobulins of 10 mg/mL. Calves fed colostrum containing less than 100 g immunoglobulin are at increased risk for failure of transfer of passive immunity. The highest levels of serum immunoglobulins are achieved by the ingestion of colostrum containing high concentrations of immunoglobulins within a few hours after birth. The concentrations of immunoglobulins in first-milking colostrum from dairy cows can vary from 20-150 g/L, with mean levels varying from 40-50 mg/mL. In one study of 919 first-milking colostrums from Holstein cows during a 4-year period on a commercial dairy farm, the colostral immunoglobulin G concentrations varied greatly, with a mean of 48.2 mg/mL and a standard deviation of 21.3 mg/mL. Immunoglobulin (Ig) concentration in colostrum is lower in first- and second-calf heifers than in third or subsequent lactations. It is also lower in colostrum from high-producing dairy cows. Natural sucking by the calf may enhance the efficiency of absorption of colostral immunoglobulins, but the volume of colostrum ingested by sucking calves is frequently inadequate. In dairy herds that allowed calves to suck naturally, the prevalence of failure of transfer of passive immunity was greater than 50% even among calves nursed by cows with above-average colostral immunoglobulin concentration. In order to ingest 100-150 g of immunoglobulins, newborn dairy calves should be artificially fed 3-4 L of fresh or refrigerated first-milking colostrum from cows that have had nonlactating intervals of normal duration. In beef cattle, the concentration of immunoglobulin in colostrum is generally higher than in dairy cattle but there can be deficiencies of volume production, especially in first-calf heifers. The maximum level of serum immunoglobulins is reached in the calf at 24 hours after birth and the factors that reduce those levels below an adequate level include the effects of maternal behavior and conformation, the vigor of the calf and environmental influences. Before the newborn calf manages to suck for the first time, a chain of specific events occurs. The calf first recovers from the birth process, attempts and is successful in standing up and then begins to search for a teat. The calf must find its dam and then locate the udder and teats. There are wide variations in the length of each interval and many factors can affect the variation in the intervals, and consequently the calf's first suck and acquisition of passive immunity. The risk of diarrhea in calves born to dams and sired by susceptible sires. Most if not all pigs have intestinal receptors for K99* pili and an inheritance pattern similar to K88* receptors does not exist for K99* receptors.

Diseases associated with Escherichia coli

The mortality rate from enteric disease is much higher in calves with low levels of serum immunoglobulins than in calves with adequate levels. From the evidence of surveys, up to 40% of newborn dairy calves do not acquire adequate levels of serum colostral immunoglobulins because they do not ingest a sufficient amount of high-quality colostrum soon enough after birth; this makes them very susceptible to neonatal disease, especially enteric disease. In New Zealand, about 50% of dairy calves may not receive colostrum from their dams even when they are left together for up to 24 hours after the birth of the calf. The failure of transfer of passive immunity be undesirable in that the calf cannot find the teat so easily on badly shaped udders or the teat may be misshapen, which makes it difficult for the calf to suck. First-calf heifers do not have as much colostrum or as wide a spectrum of specific antibodies as do mature cows.

Calves that receive their first colostrum by bucket do not acquire the same high levels of serum colostral immunoglobulins as calves which receive their first colostrum by natural sucking of the teat. In both cases the presence of the dam improves the absorption. Calves that are weak or have an edematous tongue from a prolonged, difficult parturition may not be able to suck for several hours, by which time the ability to absorb colostral immunoglobulins has decreased markedly. Postnatal respiratory acidosis in calves can adversely affect colostral immunoglobulin absorption, despite adequate colostral intake early in the absorptive period. Risk factors predictive of postnatal acidosis are duration of second-stage parturition greater than 1 hour, dystocia requiring traction, and weakness of the calf at birth. Beef calves born outdoors may be subjected to several influences that affect colostral intake. They may be born during a snowstorm and suffer severe cold exposure; when born they may be dropped in a snowbank and be unable to get up, even with the assistance of the dam. In crowded calving grounds, mismothering due to mistaken identity may occur, resulting in the calf receiving no or very little colostrum.

Certain parameters measurable in dairy calves at, or shortly after birth may have important prognostic value in evaluating the risk of calf diarrhea. High levels of serum immunoglobulins decrease the length of an episode of diarrhea. The age at onset of diarrhea may be lower in lighter and in heavier newborn calves: lighter calves may be premature and unable to suck adequately, and heavier calves may have experienced dystocia.

Dairy calves The mortality rate from enteric disease is much higher in calves with low levels of serum immunoglobulins than in calves with adequate levels. From the evidence of surveys, up to 40% of newborn dairy calves do not acquire adequate levels of serum colostral immunoglobulins because they do not ingest a sufficient amount of high-quality colostrum soon enough after birth; this makes them very susceptible to neonatal disease, especially enteric disease. In New Zealand, about 50% of dairy calves may not receive colostrum from their dams even when they are left together for up to 24 hours after the birth of the calf. The failure of transfer of passive immunity
was due primarily to calves not sucking soon enough after birth. Of the calves that did suck, the time between birth and first sucking ranged between 0.9 and 19.1 hours.

**Beef calves.** The prevalence of failure of transfer of passive immunity in beef calves in North America ranges from 11–31%. In beef cow/calf herds averaging 56 cows in Quebec, Canada, failure of transfer of passive immunity occurred in 19% of the calves. The risk factors for failure of transfer of passive immunity (serum concentrations < 10 g/L) in the newborn included being born in a stanchion-stall (odds ratio [OR] 10.2). Calves bottle-fed colostrum were less at risk of failure of transfer of passive immunity (OR = 0.06). Calf gender, month of birth, dam parity and dam body condition were not associated with failure of transfer of passive immunity.19

**Lambs.** Lambs with low serum colostral immunoglobulin levels are also highly susceptible to enteric colibacillosis. The factors related to the risk of neonatal mortality, birth weight and serum immunoglobulin concentrations in lambs in the UK indicate that low birth weight and low serum immunoglobulin concentration were associated with increased odds of mortality.13 Fifty-six percent of the variation in immunoglobulin concentration was at the lamb level, 36% at the ewe level and only 7% at the farm level. Factors associated with reduced serum immunoglobulin concentration included early or late birth in the lambing season, being born later than 14 days after the first lamb born on the farm, multiple-birth litters and maternal mastitis.

**Piglets.** Newborn piglets that do not obtain a liberal quantity of colostrum within a few hours after birth are very susceptible to colibacillosis. Prolonged parturition, weak piglets, slippery floors, cold drafty farrowing crates and the condition of the sow and her colostrum supply all influence the amount of colostrum ingested by the newborn piglet. Enteric colibacillosis is the major disease in piglets that are weaned from the sow immediately after birth and reared on milk replacers. A crude preparation of porcine immunoglobulin added to the milk replacer of Colostrum-deprived pigs provided good protection against enteric colibacillosis when fed for the experimental period of 21 days.

Environmental and management risk factors

**Meteorological influences**

While few epidemiological data are available to support the claim, many veterinarians have observed a relationship between adverse climatic conditions and colibacillosis in both calves and piglets. During inclement weather, such as a snowstorm, a common practice in beef herds is to confine the calving cows in a small area, where they can be fed and watered more easily. The overcrowding is commonly followed by an outbreak of acute diarrhea in the calves. There is evidence that cold, wet, windy weather during the winter months and hot, dry weather during the summer months has a significant effect on the incidence of dairy calf mortality.

The risk factors for mortality from diarrhea in beef calves in Alberta, Canada, have been examined.14 The odds of increased mortality were increased when the cows and heifers were wintered on the same grounds, when the herd was wintered and calved on the same grounds, and if the cows and heifers calved on the same grounds. The morbidity and mortality rates from diarrhea during the first 60 days of life increased with an increasing percentage of heifers calving in the herd. Heifers are commonly more closely confined during the calving season for more effective observation and assistance at parturition. This may lead to increased contamination of the environment and the abdominal wall and udder of the heifers. Additional factors in heifers include a higher incidence of dystocia and maternal misbehavior, and lower volume and quality of colostrum, all of which can result in weak calves that may not acquire sufficient colostral immunity.

**Nutrition and feeding methods**

Dairy calves fed milk substitutes may be more susceptible to acute undifferentiated diarrhea, some of which may be due to enteric colibacillosis, compared to those fed cows’ whole milk. Extreme heat treatment of the liquid skim-milk in the processing of dried skim-milk for use as milk substitutes for calves resulted in denaturation of the whey protein, which interferes with digestibility of the nutrients and destruction of any lactoglobulins that are present and may have a protective effect in the young calf.

Irregular feeding practices resulting in dietary diarrhea may contribute to a higher incidence of enteric colibacillosis in calves. The person feeding and caring for the calves has been an important factor influencing calf mortality due to diarrhea. While it is generally believed that general or specific nutritional deficiencies such as a lack of energy, protein or vitamin A in the maternal diet predispose to colibacillosis, particularly in calves and piglets, there is no direct evidence that specific nutritional deficiencies are risk factors. They probably are, at least in indirect ways, for example by having an effect on the amount of colostrum available at the first milking after parturition in first-calf heifers underfed during pregnancy.

**Standard of housing and hygiene**

Housing and hygienic practices are probably the most important risk factors influencing the incidence of colibacillosis in calves and piglets but have received the least amount of research effort compared to other aspects, for example control of the disease through vaccination. As the size of herds has increased, and as livestock production has become more intensified, the quality of hygiene and sanitation, particularly in housed animals, assumes major importance. Where calves are run at pasture or are individually tethered, or penned, on grass the disease is much less common.

**Source of the organism and its ecology and transmission**

Ingestion is the most likely portal of infection in calves, piglets, and lambs, although infection via the umbilical vessels and nasopharyngeal mucosa can occur. It has been suggested that certain serotypes of *E. coli* may enter by the latter route and lead to the development of meningitis.

In most species, it is assumed that the primary source of the infection is the feces of infected animals, including the healthy dams and neonates, and diarrheic newborn animals, which act as multipliers of the organisms. In some cases the organism may be cultured from the vagina or uterus of sows whose litters become affected. In pig herds the total number of organisms on each sow is highest in the farrowing barn, decreases when the sow is returned to the breeding barn, and is lowest when the sow is in the gestation barn.

**Calves.** Calves acquire the infection from contaminated bedding and calf pails, dirty calf pens, near-by diarrheic calves, overcrowded calving grounds, and from the skin of the perineum and udder of the cow. The organism is spread within a herd through the feces of infected animals, and all the inanimate objects that can be contaminated by feces, including bedding, pails, boots, tools, clothing, and feed and water supplies. The organism is one of the first encountered by newborn farm animals within minutes after birth. In cattle, the tonsil can be a reservoir for Shiga-like positive *E. coli* in healthy animals.15 It is possible that virulent *E. coli* can be present and may be transferred to calves when they are licked by their dams at birth. The high population density of animals that occurs in overcrowded calving grounds in beef herds, heavily used calving pens in dairy herds and the continuous successive use of farrowing crates without
A break for clean-up contributes to a large dynamic population of *E. coli*. The population of bacteria in an animal barn will continue to increase with the length of time the barn is occupied by animals without depopulation, clean-out, disinfection and a period of vacancy. In some countries, where lambing must be done in buildings to avoid exposure to cold weather, the lambing sheds may become heavily contaminated within a few weeks, resulting in outbreaks of septicemic and enteric colibacillosis.

Infected animals are the main reservoir for enterotoxigenic *E. coli* and their feces are the major source of environmental contamination with the bacteria. Passage of the *E. coli* through animals causes a ‘multiplier effect’, as each infected animal excretes many more bacteria than it originally ingested. Diarrheic calves are the most extreme multipliers, because they often pass 1 L or more of liquid feces containing 10<sup>9</sup>/g enterotoxigenic *E. coli* within 12 hours, and recovered calves can continue to shed bacteria for several months.

Normal calves and adult cows can serve as reservoirs of infection, and the bacteria can persist in a herd by circulating through animals of all ages. Carrier animals introduced to an uninfected herd are thought to be one of the main causes of natural outbreaks. The duration and amount of shedding probably depends on the degree of confinement, resulting population density, herd immunity, environmental conditions and perhaps the serotype of the organism.

### Pathogen risk factors

#### Virulence attributes of *E. coli*

The virulence attributes of enterotoxigenic *E. coli* include the adhesins in their pili or fimbiae that allow them to adhere to intestinal villous epithelial cells and prevent peristaltic elimination by the gut, and the production of heat-stable (ST) and heat-labile (LT) enterotoxins. The **septicemic strains** are invasive and commonly cause rapid death due to the effects of a septicemia involving multiple body systems. In animals that do not die of septicemia, localization of the bacteria may also occur in joints and other organs and tissues. Certain strains such as the O115:K:VVX 165 can cause either diarrhea or septicemia in piglets and calves.  

The virulence attributes are relevant to vaccine efficacy. The species-specific adhesin antigens must be identified and incorporated into vaccines, which are given to pregnant females in an attempt to stimulate the production of specific antibody in the colostrum, which will provide protection against enterotoxigenic colibacillosis. An essential element of vaccine development is the detection of common fimbrial antigens occurring among most pathogenic isolates and able to induce antibodies that block bacterial adhesion. The great diversity of potential pathogenic serotypes encountered in colisepticemia and the failure of serotype-specific antibody to cross-protect against a heterologous challenge in experimental infection have made it difficult to develop vaccines against septicemic colibacillosis.

#### Calves

The major virulence attributes of the **enterotoxigenic strains of *E. coli*** in calves are the K<sup>99</sup><sup>+</sup> adhesin antigen and the heat-stable enterotoxin. The colonization in the small intestine of calves by K<sup>99</sup><sup>+</sup> enterotoxigenic *E. coli* appears to be site-specific, having a predilection for the ileum. Some serogroups also elaborate the F41 adhesin to the K99. Other surface-adhesin antigens such as Att 25 and F17 have been identified on bovine enteropathogenic and septicemic *E. coli*. The F17a-positive enterotoxigenic *E. coli* strains are no longer isolated from diarrheic calves in some countries. It is postulated that the use of a vaccine including O101, K32, and H9 antigens in addition to K99 (F5) explains the strongly reduced incidence of the O101:K32:H9, K99(F5) *E. coli* clone. A K88-related fimbrial antigen occurs on some enterotoxigenic and septicemic strains.

The heat-stable enterotoxin from bovine enterotoxigenic *E. coli* has been purified and characterized. There is evidence of a form of heat-stable enterotoxin that is common to bovine, porcine, and human strains of enterotoxigenic *E. coli*.

Most strains of septicemic *E. coli* belong to certain serogroups with virulence properties that enable them to resist the defense mechanisms that would normally eliminate other *E. coli*. Septicemic strains produce endotoxin, which results in shock and rapid death, usually in calves that are less than 5 days of age and are agammaglobulinemic because of failure of transfer of colostral immunity. Isolates of *E. coli* from the blood of critically ill bacteremic calves on a calf-rearing farm in California constituted a heterogeneous group and were aerobactin positive and often resistant to the bactericidal effects of serum. The P fimbiae F11 and F165 have been identified in septicemic *E. coli* strains isolated from calves.

**Enterohemorrhagic *E. coli*** and **verocytotoxin-producing *E. coli*** are being recognized in humans and animals with increased frequency and constitute a major zoonotic concern. These organisms are members of O111, O103, O5, and O26 serogroups, and none produces heat-stable or heat-labile enterotoxin, nor do they possess the K99 pilus. They produce potent verotoxins, also known as the Shiga-like toxins, STLT1 and STLT2, and some strains, the **attaching and effacing *E. coli*** (AEEC), attach to and efface the microvilli of the enterocytes, causing diarrhea and dysentery due to a hemorrhagic colitis in calves 2–5 weeks of age. The effacing (attx1) gene and the gene coding for the Shiga-like toxin 1 (STLT1) are associated with most isolates of AEEC in cattle. They have been isolated from both diarrheic and healthy sheep and goats.

A study of the onset and subsequent pattern of shedding of verotoxin-producing *E. coli* O26, O103, O111, O145, and O157 in a cohort of beef calves on a mixed cattle and sheep farm in Scotland found that O26 was predominately shed by 94% of the calves and that 90% of the O26 isolates carried the stx1, eae, and ehc genes. *E. coli* O103 was the second most commonly shed serogroup of the tested calves and the pattern of shedding was sporadic and random. There was an absence of shedding of *E. coli* O111 and the prevalence of shedding of O145 was low. While some shedding of O157 occurred, shedding in calves was sporadic and infrequent.

For O26, O103, and O157, there was no association between shedding by calves and shedding by dams within 1 week of birth. For O26 and O103, there was no association between shedding and diarrhea, and no significant change in shedding following housing. In a sample of Australian dairy farms, calves as young as 48–72 hours had evidence of fecal excretion of Shiga-toxin-producing *E. coli*, indicating that dairy cattle are exposed to Shiga-toxin-producing *E. coli* from birth.

Calves at weaning are most likely to be infected with *E. coli* O26 or *E. coli* O157, similar to the prevalence surveys in the northern hemispheres. Naturally occurring cases of attaching and effacing lesions of the intestines in calves with diarrhea and dysentery and infected with *E. coli* O126:H11, the predominant verotoxin-producing *E. coli* in humans, have been described in the UK. Verotoxin-producing *E. coli* and Eae-positive non-verotoxin-producing *E. coli* have been isolated from diarrheic dairy calves 1–30 days of age.

*E. coli* O157 has been isolated from neonatal calves and has been implicated as a cause of diarrhea in calves. The isolates carried various virulence genes such as *Ehly*, eae, stx1, and stx2. The *Ehly* gene may be a virulence marker for bovine enterohemorrhagic *E. coli* O157 strains. Similar findings have been reported in dairy cattle herds in Brazil. Strains of *E. coli*, possessing a subtype beta intimin, normally found in human enteropathogenic *E. coli*, have been found in diarrheic calves in Brazil.
Non-O157 Shiga-toxin-producing E. coli have been isolated from diarrheic calves in Argentina and the serotypes carried virulence traits associated with increased pathogenicity in humans and cattle. Severe clinical syndromes associated with non-O157 Shiga-toxin-producing E. coli are common in children under 4 years of age and may be associated with diarrheal calves, which shed highly virulent Shiga-toxin-producing E. coli strains and could act as a reservoir and contamination source in these areas. E. coli O116, a serogroup previously associated with cases of hemolytic-uremic syndrome in humans, has been associated with an outbreak of diarrhea and dysentery in 1-16-week-old calves in India. E. coli O103:H2, a Shiga toxin strain causing disease in humans, has been isolated from calves with dysentery, and from a sheep in Australia.

Necrototoxic E. coli, which produce cytotoxic necrotizing factor, have been isolated from cattle in Northern Ireland and Spain, and from diarrheic piglets in England. NTEC1 strains from cattle, pigs, and humans can belong to the same serogroups, carry genes coding for adhesions belonging to the same families, and possess other identical virulence-associated properties, and therefore do not exclude the possibility of cross-infection between humans and farm animals in some cases. Necrotoxic E. coli were detected by tissue culture and polymerase chain reaction (PCR) in 15.8% of diarrheic dairy calves in Spain from 1-90 days of age; the majority were necrotoxic E. coli producing CNF2 and the risk increased with age. There was also a strong association between CNF2 and F17 fimbiae. The necrotoxic E. coli with their associated adhesins and toxins were present in diarrheic and septicemic calves as early as 1958 and their prevalence seems to be increasing.

Their role in causing disease needs further examination.

**Piglets**

Most enteropathogenic E. coli from neonatal pigs belong to the so-called ‘classical serogroups’ O8:K87, O45, O138:K81, O141:K85, O147:K89, O149:K91, and O157:KXVX17. Strains of these serogroups usually express and produce K88*, 987P*, or K99* pili antigens, which adhere to ileal villi, colonize intensively and cause profuse diarrhea when given to newborn pigs. The K88, K99, and 987P pili are also designated F4, F5, and F6, respectively. However, there are also some enterotoxigenic strains that produce none of the three antigens. K88* produces heat-labile enterotoxin (LT), the 987P* and the K99* do not produce LT, and all three types produce heat-stable enterotoxin STa in infant mice. Some isolates produce neither LT or STa but produce enterotoxin in ligated intestinal loops of pigs (STb). The K99* piliated strains are a major cause of enteric disease in piglets under 2 weeks of age. Strains of enterotoxigenic E. coli that produce 987P pili colonize the small intestines and cause diarrhea in neonatal pigs under 6 days of age but not older pigs. Other ‘nonclassical’ strains colonize the small intestine to a certain extent, do not strongly adhere to the intestinal epithelium, and produce enterotoxin and diarrhea in neonatal piglets. Vaccination of a sow population for several years with vaccines containing O149 and K88 antigens may change the pattern of virulent E. coli inducing neonatal diarrhea during the first week of life so that other serogroups may dominate.

The porcine enteroaggregative E. coli strains which induce fluid secretion in the intestine of piglets less than 2 weeks of age but not in older pigs are designated class 2, whereas those strains which induce fluid secretion in the intestines of older pigs are class 1 enterotoxigenic E. coli. The bovine strains of enteroaggregative E. coli have several features in common with the porcine class 2 organisms which include the possession of the 0 antigens 8, 9, 20, or 101, characterization as mucoid colonies, possession of K99* pili and production of heat-stable enterotoxin. Most strains of enteroaggregative E. coli of pigs belong to a restricted number of serogroups.

Lambs

Enterotoxigenic strains of E. coli can be isolated from the feces of approximately 35% of diarrheic lambs. Enterotoxigenic strains of E. coli have also been isolated from the blood of a small percentage of diarrheic lambs. K99 pilated E. coli are associated with outbreaks of diarrhea in lambs under a few days of age. F17 fimbiae E. coli have been isolated from diarrheic lambs and kids but none of the isolates produced any of the toxins normally associated with enteropathogenic strains. Attaching and effacing E. coli negative for verocytotoxin but positive for eae have been isolated from goat kids affected with severe diarrhea with a high case fatality rate.

**Foals**

An enterotoxigenic strain of E. coli with some evidence of K99 and F41 pilus antigens, K87 capsular antigens and serotype 101 somatic antigen has been isolated from newborn foals affected with diarrhea. However, they are not considered to be major pathogens in foals. The strains of E. coli isolated from the feces of diarrheic and healthy foals are very diverse and enteroaggregative strains of the organism are not implicated in sporadic foal diarrhea. The isolates of E. coli obtained from the blood and tissues of septic foals are different from those isolated from the feces of healthy foals. Isolates from septic foals were resistant to equine serum. Isolates of E. coli from septic foals contained conjugal plasmids that encoded resistance to multiple antimicrobial agents linked to equine serum resistance and to the production of aerobactin, which permits the growth of the organisms in an iron-limited environment, a trait considered a virulence determinant.

Zoonotic implications of E. coli

Cattle are a major source of E. coli O157:H7, which infects and causes food-borne disease in humans. Several strains of enterohemorrhagic E. coli associated with enteric disease in humans produce a verotoxin also known as a Shiga-like toxin. The literature on the epidemiology and virulence mechanisms of E. coli O157:H7 has been reviewed. (See ‘Enterohemorrhagic Escherichia coli in farm animals and zoonotic implications’, below).

**PATHOGENESIS**

The factors important in understanding the pathogenesis of colibacillosis are the immune status of the animal and the virulence attributes of the strain of E. coli, particularly its capacity to invade tissues and produce a septicemia, or to produce an enterotoxin that causes varying degrees of severity of diarrhea. Septicemia, bacteremia, diarrhea, dehydration, and metabolic acidosis are the major pathogenetic events in the various forms of colibacillosis.

**Septicemic colibacillosis (coliform septicemia)**

This occurs in all species as a result of invasive strains of E. coli invading the tissues and systemic circulation via the intestinal lumen, nasopharyngeal mucosa, and tonsillar crypts, or umbilical vessels. The intestinal permeability to macromolecules in the newborn piglet may predispose to the invasion of septicaemia-inducing E. coli. These strains are able to invade extraintestinal tissues, to resist the bactericidal effect of complement, to survive and multiply in body fluids, to escape phagocytosis and intracellular killing by phagocytes, and to induce tissue damage by the release of cytotoxins. Calves and piglets that are deficient in colostral immunoglobulins are highly susceptible to septicemia. Colostrom provides protection against colisepticaemia but may not prevent diarrhea associated with E. coli. Also, colostrum-fed calves are much more resistant to endotoxin than colostrum-deprived calves. Calves, piglets, and lambs that have normal levels of serum
immunoglobulins are generally protected from septicemia. The clinical findings and lesions in septicemic colibacillosis are attributable to the effects of endotoxin, which causes shock. The general effects of endotoxin in cattle include hypothermia, decreased systemic blood pressure, tachycardia and decreased cardiac output, changes in blood counts, alterations in blood coagulation, hyperglycemia followed by hypoglycemia, and depletion of liver glycogen. Animals that recover from septicemia or bacteremia may develop lesions due to localization in other organs at varying periods of time later. Arthritis is a common sequel in calves, foals, and lambs. Meningitis is common in calves and piglets. Polyserositis due to E. coli has been recorded in pigs.

**Enteric colibacillosis**

Enterotoxigenic colibacillosis

Enterotoxigenic strains of E. coli colonize and proliferate in the upper small intestine and produce enterotoxins, which cause an increase in net secretion of fluid and electrolytes from the systemic circulation. The adhesion of E. coli to the intestinal epithelial cells is mediated by bacterial pili. The enterotoxigenic form of colibacillosis occurs most commonly in calves and piglets and less commonly in foals and lambs.

The factors that allow or control the colonization and proliferation of these strains and their production of enterotoxin are not well understood. The bacterial fimbrae attach to specific receptor sites on villous epithelial cells, following which the bacteria multiply and form microcolonies that cover the surface of the villi. The capsular polysaccharide of E. coli may also be involved in adhesion and colonization. The fimbrae of E. coli are strongly immunogenic, a factor that is utilized in the production of vaccines. Experimentally, the intestinal fluid from the most proximal small intestine of calves is more suppressive of K99 pilus expression than fluid from more distal segments of the small intestine. Thus any factor that results in an increase of the pH in the lumen may allow the proliferation of the organism and, conversely, lowering the pH may reduce the severity of colibacillosis.

Diarrhea, dehydration, metabolic acidosis and electrolyte imbalance

The production of the enterotoxin results in net secretion of fluid and electrolytes from the systemic circulation into the lumen of the intestine, resulting in varying degrees of diarrhea, dehydration, electrolyte imbalances, acidosis, hyperkalemia when the acidosis is severe, circulatory failure, shock and death. The hyperkalemia in calves with neonatal diarrhea and acidosis has been associated with cardiac rate and rhythm abnormalities, including bradycardia and atrial standstill. The response to the enterotoxin in calves and piglets is similar to cholera enterotoxin in humans and takes place through an intact mucosa. Enterotoxin stimulates mucosal adenylcyclase activity, leading to an increase in cyclic adenosine monophosphate (AMP), which increases intestinal fluid secretion. The secretion originates primarily in the intestinal crypts but the villous epithelium also has a secretory function. The fluids secreted are alkaline and, in comparison to serum, isotonic, low in protein and high in sodium and bicarbonate ions. Distension of the right abdomen of diarrheic calves may occur, which may be associated with fluid distension of the abomasum and the intestines.

When the disease is confined to the intestine, it responds reasonably well to treatment in the early stages. If death occurs, it is due to acidosis, electrolyte imbalance, and dehydration. The acid-base and electrolyte changes in piglets 1-3 days of age infected naturally and experimentally with enterotoxigenic E. coli reveal a severe dehydration and metabolic acidosis.

Severe metabolic changes can occur in calves with diarrhea. If the disease is progressive, the acidosis becomes more severe, lactic acidosis develops because of a reduced ability to utilize lactic acid, and severe hypoglycemia may occur because of a reduced rate of conversion of lactic acid to glucose. If extensive fluids are lost, hypovolemia and shock occur. The blood oxygen-binding capacity may be impaired in calves with diarrhea and severe dehydration.

The most commonly accepted explanations of the metabolic acidosis in diarrheal calves are fecal bicarbonate loss and l-lactic acidosis. L-lactic acidosis is thought to occur from inadequate perfusion because of dehydration or endotoxemia, with subsequent anaerobic glycolysis and decreased clearance of l-lactate. However, neonatal diarrheal calves have high serum concentrations of d-lactate, with relatively low serum l-lactate concentrations.

D-lactate acidosis is a contributory factor in calves with high anion gap acidosis. The anion gap significantly correlates with d- and total dl-lactate concentrations in serum but not with serum l-lactate concentrations. The elevated serum and urine concentrations of serum D-lactate are probably gastrointestinal in origin and the rumen and colon in diarrheic calves are considered as sites for the sources of d-lactate.

The anion gap is defined as the sum of the major cations minus the sum of the major anions and is a measure of ‘unmeasured anions’:

$$\text{Anion gap} = [\text{Na}^+] + [\text{K}^+] - [\text{Cl}^-] - [\text{HCO}_3^-]$$

The anion gap may be changed in numerous disturbances, including those of acid-base imbalance, and is useful in the interpretation of acid-base findings, but is of no value in assessing the intrinsic severity of acid-base disturbances.

Diarrheic calves are generally hyperkalemic with a high serum anion gap, a depressed serum bicarbonate and a low blood pH.

The severity and nature of the acidosis in diarrheal calves varies with the age of the calf. Diarrheic calves under 1 week of age often have a lactic acidosis, while those over 1 week of age have a nonlactic acidosis. Younger calves tend to dehydrate more rapidly and severely than older calves, which may be related to the greater incidence of enterotoxigenic colibacillosis in the young age group. The severity of dehydration, hypothermia, and metabolic acidosis is associated with the level of mental depression. The clinical signs and age of the calf can be used to predict the severity of acidosis; the more severe the acidosis, the greater the depression.

Metabolic acidosis without clinical evidence of dehydration occurs in some calves that have had a history of diarrhea in the previous several days. A similar syndrome has been described in goat kids. The pathogenesis is unclear but is thought to be associated with diarrhea in the preceding several days. Possibility is an inadequate amount of bicarbonate in the fluids and electrolytes used for the treatment of the dehydration.

**Hyperkalemia in the diarrheic calf**

Hyperkalemia is most common in dehydrated diarrheic calves that are severely acidic. The potassium moves out of the intracellular space into the extracellular space, resulting in hyperkalemia. The predominant clinical finding is bradycardia (heart rate < 90 bpm) in a dehydrated diarrheic calf. However, hypoglycemia and metabolic acidosis may be associated with bradycardia in a similar calf.

**Hypernatremia in the diarrheic calf**

Acute hypernatremia may occur in diarrheal calves. Clinical findings are nonspecific and include depression, weakness, dehydration, and diarrhea. Laboratory determination of serum electrolytes is necessary to make the diagnosis. The serum sodium concentration is above 160 mEq/L. It is presumed that mixing errors in the preparation of oral electrolyte solutions for diarrhea is the cause. The experimental oral administration of 1 L of electrolyte concentrate containing...
In general, enterotoxigenic E. coli enterocytes will produce heat-stable enterotoxin which will induce microscopic alterations of the villous epithelium. Focal emigration of neutrophils, especially through the epithelium above aggregated lymphatic follicles, stunning of jejunal and ileal villi, and adherence of bacteria to jejunal ileal mucosa are the most consistent finding. These changes are useful in making the diagnosis of enterotoxigenic colibacillosis in calves. While enterotoxigenic strains are considered to be noninvasive this does not preclude the possibility that invasion into the systemic circulation may occur, resulting in septicaemia, or that septicaemic strains may not also be present.

Enzyme histochemistry studies of the small intestinal mucosa in experimental infections of calves with rotavirus and enterotoxigenic E. coli indicate a marked decrease in enzyme activity in dual infections and a lesser decrease in mono-infections. Increased enzyme activity occurred in parts of the intestinal mucosa that were not affected or only slightly affected by the enteropathogens, which may be an adaptation of the mucosa to maintain absorptive function. Lactose digestion is slightly impaired in calves with mild diarrhoea. Calves with acute diarrhea are in a catabolic state and respond with a larger increase of plasma glucose concentration to a given amount of absorbed glucose than do healthy calves. Fat and carbohydrate malabsorption frequently occurs in diarrheic calves over 5 days of age and may contribute to the death of these animals in cold weather.

Attaching and effacing colibacillosis
Attaching and effacing enteropathogenic E. coli can cause naturally occurring diarrhoea and dysentery in calves at 18–21 days. They do not produce enterotoxin but adhere to the surface of the enterocytes of the large intestine. Affected calves pass bright red blood in the diarrheic feces. The lesions in experimentally infected calves are indistinguishable from those produced by some E. coli that are enteropathogenic for humans, rabbits, and pigs. They do not produce enterotoxin. The bovine O118:H16 enterohemorrhagic E. coli strain is able to colonize the intestine of newborn calves and to induce diarrhea 24 hours after challenge and to produce attaching and effacing lesions in the small and large intestines.

Synergism between enteropathogens
Enterotoxigenic colibacillosis occurs naturally and can be reproduced experimentally using enterotoxigenic E. coli in calves under 2 days of age but not in calves 1 week of age. Diarrheic calves older than 3 days of age may be infected with enterotoxigenic K99* E. coli and rotavirus. There is evidence that prior or simultaneous infection of the intestine with rotavirus will enable the E. coli to colonize in older calves. Thus, there may be synergism between rotavirus and enterotoxigenic E. coli in calves older than 2 days; this may explain the fatal diarrhoea that can occur in calves at 1 week of age, which normally would not be fatal with a single infection. The rotavirus may enhance colonization of the E. coli. In the Kashmir valley of India, diarrheic lambs from birth to 3 months of age are commonly infected with group A rotaviruses and pathogenic serogroups of E. coli O26, O113, O157, all of which are pathogenic to humans.

The simultaneous experimental infection of neonatal gnotobiotic calves at 24 hours of age with rotavirus and enterotoxigenic E. coli results in a severe diarrhoeal disease. The same situation occurs in piglets. However, in both species the effect is additive rather than synergistic.

Summary of pathogenesis
Septic colibacillosis occurs in newborn animals that are agammaglobulinemic because they have not ingested sufficient colostrum early enough, or have absorbed insufficient colostral immunoglobulins, thus rendering them highly susceptible. Enteric colibacillosis occurs in colostrum-fed animals and is associated with the colonization and proliferation of enteropathogenic E. coli, which produce enterotoxin and cause varying degrees of diarrhea and acidosis and dehydration. While single infections occur commonly, in piglet diarrhoea, and what was previously described as enteric-toxemic colibacillosis in calves, multiple infections with enteropathogenic E. coli and viruses and other agents are more common.

CLINICAL FINDINGS
Calves
Coliform septicaemia
This is most common in calves during the first 4 days of life. Most affected calves have low levels of serum colostal immunoglobulins because of inadequate transfer of colostral immunoglobulins. The illness is peracute, the cause varying from 24–96 hours with a survival rate of less than 12%. There are no diagnostic clinical signs. Affected animals are depressed and weak, commonly recumbent, and dehydrated; tachycardia is present and, although the temperature is often normal, there may be a high initial, and high very high, respiratory rate. The suck reflex is weak or absent, the oral mucous membranes are dry and cool, and the capillary refill time may be prolonged. Cold extremities, weak peripheral pulse and prolonged
Enteric colibacillosis

This is the most common form of colibacillosis in newborn calves, primarily 3–5 days of age. It may occur in calves as early as 1 day of age and only rarely up to 3 weeks. The clinical severity will vary depending upon the number and kind of organisms causing the disease. The presence of a single enterotoxigenic strain of E. coli may cause a state of collapse usually designated as enteric toxemia. In this form of the disease the outstanding clinical signs include severe weakness, coma, subnormal temperature, a cold clammy skin, pale mucousae, wetness around the mouth, collapse of superficial veins, slowness and irregularity of the heart, mild convulsive movements, and periodic apnea. Diarrhea is usually not evident, although the abdomen may be slightly distended and succussion and auscultation may reveal fluid-splashing sounds suggesting a fluid-filled intestine.61

The prognosis for these calves is poor and they commonly die 2–6 hours after the onset of signs.

In the more common form of the disease in calves, there is diarrhea in which the feces are profuse and watery to pasty, usually pale yellow to white in color, and occasionally streaked with blood flecks and very foul-smelling. The dry matter content of the feces is commonly below 10%. Defecation is frequent and effortless, and the tail and perineum are soiled with feces. The temperature is usually normal in the initial stages but becomes subnormal as the disease worsens. Affected calves may or may not suck or drink depending on the degrees of acidosis, dehydration, and weakness. Calves under 8 days of age may be weak, primarily from the effects of rapid and severe dehydration; in calves older than 8 days the acidosis may be more severe and makes a greater contribution to depression and weakness. In the early stages of the disease, the abdomen may be slightly distended as a result of distension of fluid-filled intestines, which can be detected by succussion and auscultation of the abdomen. In some of these calves the diarrhea is not obvious but is delayed for several hours, when it can be quite profuse. Mildly to moderately affected calves may be diarrheic for a few days and recover spontaneously with or without treatment. However, 15–20% of calves with enteric colibacillosis become progressively worse over a period of 3–5 days, gradually become more weak, lose the desire to suck and progressively appear more obviously clinically dehydrated.

Throughout the course of the diarrhea the degree of dehydration will vary from just barely detectable clinically (4–6% body weight (BW)) to up to 10–16% of body weight. It is best assessed by ’tenting’ the skin of the lateral portion of the cervical region and measuring the time required for the skin fold to return to normal.56 In calves with 8% of dehydration, 5–10 seconds will be required for the skin fold to return to normal; in 10–12% dehydration up to 30 seconds. Recession of the eyeball (enophthalmos) is a reliable and obvious indication of the degree of dehydration. Slight sinking of the eyeball without an obvious space between the eyeball and the orbit represents 6–8% dehydration; moderate separation of the eyeball from the orbit represents 9–12% dehydration; and marked separation of the eyeball from the orbit represents over 12% and up to 16% dehydration. A summary of the relationship between degree of dehydration (% BW), depth of enophthalmos (mm), cervical skin tent duration in seconds and the state of the mucous membranes and extremities in calves with experimentally induced diarrhea is set out in Table 18.4.56

Death usually occurs in 3–5 days. Affected calves can lose 10–16% of their original body weight during the first 24–48 hours of the diarrhea. The hyperkalemia in calves with neonatal diarrhea and acidosis has been associated with cardiac rate and rhythm abnormalities including bradycardia and atrial standstill. Herd outbreaks of the disease in beef calves may last for several weeks, during which time almost every calf will be affected within several days after birth. Veal calf hemorrhagic enteritis is a fatal syndrome of veal calves characterized by sudden death, anemia, and severe hemorrhage in the subcutaneous tissues and internal organs. The disease is primarily seen in veal calves under 2 months of age and is caused by a strain of Escherichia coli designated as enterohemorrhagic E. coli 0157:H7. The clinical signs are similar to those of hemorrhagic disease in swine caused by E. coli 0178:H7. However, veal calf hemorrhagic enteritis is characterized by a higher incidence of death and a longer duration of illness.

## Predictors of septicemia

The early clinical findings of septicemia in neonatal foals and calves are vague and nonspecific and are often indistinguishable from the findings of noninfectious diseases or those of focal infections such as diarrhea. Positive blood cultures are required for a definitive diagnosis of septicemia, but results are not usually available for 48–72 hours, and false negatives are common. A clinical sepsis scoring system for predicting bacteremia in neonatal dairy calves has been described but has not been adequately evaluated in the field.53,54

No single laboratory test has emerged as being completely reliable for the early diagnosis of septicemia in farm animal neonates and therefore scoring systems and predictive models using obtainable historical, clinical and clinicopathological data have been developed. The goal of these mathematical models is to identify septicemic neonates early in the course of disease when appropriate therapy would be most likely to result in a favorable outcome.55 In a study of diarrheic calves under 28 days of age submitted to a referral clinic for treatment, 31% of the calves were septicemic, based on blood culture.56 Two models to predict septicemia were used. Clinicopathological variables associated with an increased risk of septicemia were moderate (1.99–5.55 mg/dL) and marked (>5.66 mg/dL) increases in serum creatinine (OR 8.63), moderate to marked toxic changes in neutrophils (OR 2.88), and failure of transfer of passive immunity (IgG concentrations β 800 μg/dL, globulin β 2 g/dL (OR 2.72), and total serum protein β 5 g/dL). The clinical variables associated with an increased risk of septicemia were age under 5 days (OR 2.58), focal infection (OR 2.45), recumbency (OR 2.98), and weak suck reflex (OR 4.10).55

## Newborn calf encephalitis

The term ‘newborn calf encephalitis’ is often used colloquially in the veterinary profession. It is a combined term for a number of different conditions affecting the nervous system of newborn calves. The term is often used in the context of outbreaks of disease in which a wide range of clinical signs are observed. The signs may include weakness, ataxia, tremors, convulsions, and opisthotonos. The disease may be associated with fever, but fever is not a consistent finding. The disease is most commonly seen in newborn calves, but cases have been reported in older calves. The disease is usually not seen in calves born to dams that have been exposed to the disease in the past. The disease is caused by a variety of pathogens, including Escherichia coli, Salmonella typhimurium, and Mycoplasma bovis. The disease is characterized by a combination of central nervous system (CNS) and peripheral nervous system (PNS) signs. The CNS signs include tremors, convulsions, and opisthotonos. The PNS signs include weakness, ataxia, and hyperesthesia. The disease is often associated with fever, but fever is not a consistent finding. The disease is usually self-limiting, but fatalities can occur. The disease is often associated with other diseases, such as pneumonia and septicemia. The disease is usually not seen in calves born to dams that have been exposed to the disease in the past. The disease is caused by a variety of pathogens, including Escherichia coli, Salmonella typhimurium, and Mycoplasma bovis. The disease is characterized by a combination of central nervous system (CNS) and peripheral nervous system (PNS) signs. The CNS signs include tremors, convulsions, and opisthotonos. The PNS signs include weakness, ataxia, and hyperesthesia. The disease is often associated with fever, but fever is not a consistent finding. The disease is usually self-limiting, but fatalities can occur. The disease is often associated with other diseases, such as pneumonia and septicemia. The disease is usually not seen in calves born to dams that have been exposed to the disease in the past. The disease is caused by a variety of pathogens, including Escherichia coli, Salmonella typhimurium, and Mycoplasma bovis. The disease is characterized by a combination of central nervous system (CNS) and peripheral nervous system (PNS) signs. The CNS signs include tremors, convulsions, and opisthotonos. The PNS signs include weakness, ataxia, and hyperesthesia. The disease is often associated with fever, but fever is not a consistent finding. The disease is usually self-limiting, but fatalities can occur. The disease is often associated with other diseases, such as pneumonia and septicemia. The disease is usually not seen in calves born to dams that have been exposed to the disease in the past. The disease is caused by a variety of pathogens, including Escherichia coli, Salmonella typhimurium, and Mycoplasma bovis. The disease is characterized by a combination of central nervous system (CNS) and peripheral nervous system (PNS) signs. The CNS signs include tremors, convulsions, and opisthotonos. The PNS signs include weakness, ataxia, and hyperesthesia. The disease is often associated with fever, but fever is not a consistent finding. The disease is usually self-limiting, but fatalities can occur. The disease is often associated with other diseases, such as pneumonia and septicemia. The disease is usually not seen in calves born to dams that have been exposed to the disease in the past. The disease is caused by a variety of pathogens, including Escherichia coli, Salmonella typhimurium, and Mycoplasma bovis.
terized by anorexia, fever, diarrhea with mucus-containing feces which become bloody in the later stages, and hemorrhagic diathesis on the conjunctivae and mucous membranes of the mouth and nose. The etiology is unknown; the *E. coli* strains isolated from the feces of affected calves produced enterotoxins and verocytotoxins but their significance is uncertain.

In some calves between 10 and 20 days of age with a history of diarrhea in the previous several days, from which they have recovered, there will be metabolic acidosis without clinical signs of dehydration. Affected calves are depressed, weak, ataxic and sometimes recumbent, and appear comatose. Affected calves respond quickly to treatment with intravenous sodium bicarbonate. A similar syndrome occurs in goat kids.

**Lambs and goat kids**

Although some cases manifest enteric signs, and chronic cases may occur, colibacillosis in lambs is commonly septicemic and peracute. Two age groups appear to be susceptible: lambs 1–2 days of age and lambs 3–8 weeks old. Peracute cases are found dead without premonitory signs. Acute cases show collapse and occasionally signs of acute meningitis manifested by a stiff gait in the early stages, followed by recumbency with hyperesthesia and tetanic convulsions. Chronic cases are usually manifested by arthritis. The disease in goat kids is similar to that in lambs.

**Piglets**

**Coliform septicemia**

This is uncommon but occurs in piglets within 24–48 hours of birth. Some are found dead without any premonitory signs. Usually more than one, and sometimes the entire litter, are affected. Severely affected piglets seen clinically are weak, almost comatose, appear cyanotic, and feel cold and clammy and have a subnormal temperature. Usually there is no diarrhea. The prognosis for these is poor and most will die in spite of therapy.

**Enterotoxigenic colibacillosis (newborn piglet diarrhea)**

This is the most common form of colibacillosis in piglets and occurs from 12 hours of age up to several days of age, with a peak incidence at 3 days of age. As with the septicemic form, usually more than one pig or the entire litter is affected. The first sign usually noticed is the fecal puddles on the floor. Affected piglets may still nurse in the early stages but gradually lose their appetite as the disease progresses. The feaces vary from a pasty to watery consistency and are usually yellow to brown in color. When the diarrhea is profuse and watery there will be no obvious staining of the perineum and hindquarters with feces but the tails of the piglets will be straight and wet. The temperature is usually normal or subnormal. The disease is progressive; diarrhea and dehydration continues, the piglets become very weak and lie in lateral recumbency and make weak paddling movements. Within several hours they appear very dehydrated and shrunk, and commonly die within 24 hours after the onset of signs. In severe outbreaks the entire litter may be affected and die within a few hours of birth. The prognosis is favorable if treatment is started early before significant dehydration and acidosis occur.

**CLINICAL PATHOLOGY**

**Culture and detection of organism**

If septicemia is suspected, blood should be submitted for isolation of the organism and determination of its drug sensitivity. Blood for culture is taken aseptically from the jugular vein and inoculated directly into brain–heart infusion broth. At least one additional blood sample is taken a few hours later in order to enhance recovery rate and confirm septicemia.

The **definitive etiological diagnosis of enteric colibacillosis** depends on the isolation and characterization of the *E. coli* from the intestines and the feces of affected animals. The best opportunity of making a diagnosis is when untreated representative affected animals are submitted for pathological and microbiological examination. The distribution of the organism in the intestine and determination of the presence of K88+, K99+ or 987P+ antigens, the demonstration of enterotoxin by infant mouse test or ligated intestinal loops, and the histopathological appearance of the mucosa all contribute to the diagnosis.

The routine culture of feces and intestinal contents for *E. coli* without determining their virulence determinants is of limited value. The laboratory tests used to identify enterotoxigenic K99+ *E. coli* include a direct fluorescent antibody technique with conventional culturing methods and the ELISA, with or without monoclonal antibody, to detect the organism or the enterotoxin in the feces. DNA:RNA probes specific for genes encoding enterotoxin and adhesins are available and are being used to evaluate *E. coli* isolated from diarrheic animals. Isolates of the organism can also be examined for the presence of toxins using an enzyme immune assay test and latex agglutination test.

Detection of verocytotoxin *E. coli* in feces has relied on cytotoxicity testing and DNA hybridization. Several ELISAs are available, and monoclonal antibodies to the verocytotoxins VT1 and VT2 have been used to examine feces from animals. The isolation of *E. coli* O157:H7 has relied on its ability to ferment sorbitol. A sandwich ELISA using monoclonal antibodies to *E. coli* verocytotoxins 1 and 2 for capture and detection is available for detection of verocytotoxin-producing *E. coli* in animal feces. A PCR test is also available for detection of verocytotoxin genes in *E. coli* isolated from cattle, sheep, and pigs affected with diarrhea.

The determination of drug sensitivity of the *E. coli* isolated from the feces of diarrheic animals and piglets is currently done but is of limited value without determining which isolate is enteropathogenic.

**Hematology and serum biochemistry**

A total and differential leukocyte count and remarkable changes in the fibrinogen concentration may indicate the presence of a septicemia or severe intestinal infection. However, severely affected calves may not have grossly abnormal hemograms. In enteric disease, the major changes in plasma composition are dehydration, electrolyte imbalance, and acidosis. The total plasma osmolality is decreased. The changes in the blood biochemical and hematological profile of normal neonatal calves with age have been described.

The packed cell volume and the total solids concentration of the blood will indicate the degree of dehydration, and the blood urea nitrogen may be increased in severe cases because of inadequate renal perfusion. The blood bicarbonate values are markedly reduced, blood pH values represent acidosis, and the other serum electrolytes are variable. Calves with a venous blood pH below 7.0 are at risk and require immediate parenteral therapy for acidosis. There is usually a decrease in serum sodium, chloride, and potassium. In severe cases of acidosis, hematologic changes may occur; this is cardiotoxic and affected calves may die while being handled in preparation for intravenous therapy.

**Harleco apparatus**

The acid–base status of individual calves can be determined in the field using a simple total carbon dioxide apparatus, which provides values close to blood bicarbonate concentrations. Unlike the blood gas machines, the Harleco apparatus offers clinicians in practice an affordable means of diagnosing metabolic acidosis. The Harleco measures ‘total carbon dioxide’, the carbon dioxide liberated from a blood sample by adding strong acid. Nearly all the carbon dioxide is derived from bicarbonate rather than blood carbon dioxide. The CO₂ liberated is derived from bicarbonate and from dissolved CO₂ but there is so little dissolved CO₂ in blood that the TCO₂ may be taken directly as mEq/l without correction for dissolved CO₂.
be taken for clinical purposes as a measurement of plasma bicarbonate. The level of acidosis in calves can be classified according to the Harleco readings (total carbon dioxide, mmol/L) as follows:

- Normal: 21.1–28
- Mild: 16.6–21
- Moderate: 12.1–16.5
- Severe: 8.1–12.0
- Very severe: < 8.

The strong ion difference method of evaluating acid–base balance in cattle has been described and justified to identify the mechanism for a change in acid–base balance and thereby to focus treatment on the inciting cause, and to quantify unmeasured strong anion concentration in plasma. A comparison of the measurement of total carbon dioxide and strong ion difference (SID) for the evaluation of metabolic acidosis in calves did not find any advantage to the SID.

Portable pH meter
A portable pH meter has been evaluated to measure blood pH in neonatal calves. Compared to a blood gas analyzer, the portable pH meter was more accurate in measuring urine pH and ruminal fluid pH in cows than blood pH in neonatal calves.

Serum immunoglobulins
The determination of the level of serum immunoglobulins of diarrheic calves may be valuable in assessing prognosis and to determine the intensity of the therapy required for survival. However, the level of serum immunoglobulins as a measure of susceptibility or prognosis is most accurate at 24 hours after birth. After this period, it is unreliable because the serum immunoglobulins may be increased in response to septicemia, increased sparsely in dehydration and decreased in enteric disease.

Several tests are available to assess transfer of passive immunity status in domestic animals. The radial immunodiffusion test and the ELISA are the only tests that directly measure serum IgG concentration. All other available tests, including serum total solids by refractometry, sodium sulfite turbidity tests, zinc sulfate turbidity tests, serum gamma-glutamyl transferase (GGT) and whole-blood glutaraldehyde coagulation, estimate serum IgG concentration based on concentration of total globulins or other proteins whose transfer is statistically associated with that of IgG.

Radial immunodiffusion
The radial immunodiffusion is the gold standard for measurement of serum IgG concentration. However, it is too expensive for most situations and requires considerable time before results are available.

Commercial immunoassay
An immunoassay using blood is now available for evaluating transfer of passive immunity in calves. The whole blood immunoassay kit consists of a 4 mm lateral flow membrane strip enclosed in a plastic test device. Test kits are incubated for 20 minutes. If the sample IgG concentration is 10 mg/mL or more, a single red line develops, indicating adequate transfer of passive immunity and a negative test result. If the sample IgG concentration is <10 mg/mL, two lines develop on the membrane strip, indicating failure of transfer of passive immunity and a positive test result. The sensitivity and specificity of the blood IgG immunoassay were 0.93 and 0.88 respectively, compared with 1.00 and 0.53 for the sodium sulfite test. For refractometry, sensitivity and specificity were 0.71 and 0.83 respectively, when a serum total solids concentration of 5.2 g/dL was used as the cutoff between positive and negative results.

Sodium sulfite turbidity test
The sodium sulfite turbidity test is a three-step semiquantitative test using 1, 4, 16, and 18% sodium sulfite test solutions. The solutions cause selective precipitation of high-molecular-weight proteins, including immunoglobulins. Optimum diagnostic utility is attained using a 18% test solution. The mean serum IgG concentrations of calves at the 1+, 2+, and 3+ endpoints of test turbidity were 1250, 2116, and 2948 mg/dL, respectively.

Serum gamma-glutamyl transferase activity
The serum levels of GGT are also reliable indicators of the level of transfer of passive immunity in newborn calves. Calves classified as having failure of transfer of passive immunity (<800 mg IgG/dL) had a 9.5 times greater risk of becoming sick prior to weaning at 5 months of age compared with calves determined to have partial failure of transfer of passive immunity and clinically normal calves. In 1-week-old calves, serum GGT activity should be more than 200 IU/L; in 4-day-old calves it should be more than 100 IU/L and in 1-week-old calves more than 75 IU/L. Calves with GGT activity below 50 IU/L within the first 2 weeks of life should be considered to have failure of transfer of passive immunity. The sensitivity and specificity of cutoff value of 200 IU of GGT of serum for a diagnosis of failure of transfer of passive immunity are 80% and 97%, respectively. The sensitivity and specificity of a cutoff value of 4.2 g of protein/dL of serum for diagnosing failure of transfer of passive immunity were 80% and 100%, respectively.

Recent studies have shown that GGT activity has no apparent advantage relative to other tests for predicting transfer of passive immunity in beef calves.

The relationships between serum and colostrum/milk GGT activities and IgG concentration can be used to assess the transfer of passive immunity status of lambs. Regression models were used to calculate serum and colostrum/milk GGT activities, and it was moderately accurate in predicting serum IgG concentration. The GGT activity can be used as an alternative to single radial immunodiffusion, which is complex, expensive, and time-consuming for estimation of IgG concentration.

**NECROPSY FINDINGS**

In case of coliform septicemia there may be no gross lesions and the diagnosis may depend upon the isolation of the organism from the filtering organs. In less severe cases there may be suberosal and submucosal hemorrhages. A degree of enteritis and gastritis may be present. Occasionally, fibrinous exudates are found...
in the joints and serous cavities, and there may be emphysema, pneumonia, and meningitis. The histological features of such presentations of colibacillosis are those of septicaemia and toxemia.

In enteric colibacillosis of piglets and calves the carcass appears dehydrated but the intestine is flaccid and fluid-filled. In calves, the abomasum is usually distended with fluid and may contain a milk clot. This clot is typically absent in calves fed milk replacers containing heat-denatured skim milk powder or noncasein milk products such as whey powder. The abomasal mucosa may contain numerous small hemorrhages. In both calves and pigs, the intestinal mucosae may appear normal or hyperemic and there may be edema of the mesenteric lymph nodes. Mild atrophy or even fusion of jejunal and ileal villi is often seen, but the key microscopic observation is the presence of bacilli adherent to the brush borders of enterocytes. Ultrastructurally, there is increased epithelial cell loss from the villus about 12 hours after experimental inoculation of calves with an enterotoxigenic E. coli.

In calves affected with attaching and effacing E. coli there is pseudomembranous ileitis as well as mucohemorrhagic colitis and proctitis. Microscopic examination of well-preserved gut segments reveals bacterial adherence, atrophy of ileal villi, and erosion of enterocytes.

In addition to traditional bacteriological culture techniques, the enterotoxigenic E. coli may be identified by several tests, including indirect fluorescent antibody tests (IFA) specific for K88*, K99*, and 987P plus antigens. The IFA tests can be performed on impression smears or frozen sections of ileal tissue and the results are available within a few hours. Other techniques such as DNA gene probes, enzyme immune assays and latex agglutination tests are now available to identify those isolates that are enterotoxin producers and have adhesin properties.

During severe disease outbreaks it is often necessary to conduct the necropsy examination on diarrheic animals that have been killed specifically for the purpose of obtaining a definitive etiological diagnosis. The combined use of bacteriological, parasitological, and virological methods, together with histological and immunofluorescent studies of fresh intestinal tissue, will provide the most useful information about the location of the lesions and the presence of enteropathogens. Postmortem autolysis of the intestinal mucosae and invasion of the tissues by intestinal microflora occurs within minutes after death, so gut samples should be collected immediately following euthanasia of the animal.

**Samples for confirmation of diagnosis**

Coliform septicaemia
- Bacteriology – chilled spleen, lung, liver, culture swabs of exudates, umbilicus, meninges (CULT)
- Histology – fixed samples spleen, lung, liver, kidney, brain, and any gross lesions

Enteric colibacillosis
- Bacteriology – chilled segments of ileum and colon (including content) (CULT and/or FAT, latex agglutination, PCR)
- Histology – fixed duodenum, jejunum, ileum, colon, and mesenteric lymph node.

**DIFFERENTIAL DIAGNOSIS**

The definitive etiological diagnosis of septicaemic colibacillosis is dependent on the laboratory isolation of the causative agent, which is usually a single species or organism. The septicaemias of the newborn cannot be distinguished from each other clinically. The definitive etiological diagnosis of enteric colibacillosis in newborn calves and piglets may be difficult and often inconclusive because of the significance of other organisms in the intestinal tract and feces of diarrheic animals cannot be easily determined.

Table 18.3 lists the possible causative agents of diarrhea and septicemia in newborn farm animals. Using the combined diagnostic approach of detection of enteropathogens in the feces before death, and in the intestinal mucosa after death, it is possible to identify where enterotoxigenic E. coli, rotavirus, coronavirus, Salmonella sp, and Cryptosporidium sp. appear to be the only or principal causative agents. However, as described earlier under acute undifferentiated diarrhea of newborn farm animals, mixed infections are more common than single infections.

Every effort that is economically possible should be made to obtain an etiological diagnosis. This is especially important when outbreaks of diarrhea occur in a herd or where the disease appears to be endemic. The use of an interdisciplinary approach will increase the success of diagnosis. This includes making a visit to the farm or herd and making a detailed epidemiological investigation of the problem. The diagnosis depends heavily on the epidemiological findings, the microbiological and pathological findings, and sometimes on the results of treatment.

The major difficulty is to determine whether or not the diarrhea is infectious in origin and to differentiate it from dietetic diarrhea, which is most common in hand-fed calves and in all newborn species that are sucking high-producing dams. In dietetic diarrhea the feces are voluminous and pasty to gelatinous in consistency; the animal is bright and alert and is usually still sucking, but some may be inappetent.

**TREATMENT**

Coliform septicaemia

**Intensive critical care** is required for the treatment of neonatal coliform septicaemia. Early identification of septicaemia and early therapeutic intervention can improve treatment success. While E. coli may be cultured from the blood of septicaemic calves, a significant percentage of isolates are Gram-positive, which justifies the use of antimicrobials that have a broad spectrum.

Antimicrobials are given parenterally and may be given continuously intravenously, more than once daily and daily until recovery is apparent. Isolation of the organisms from blood and determination of drug sensitivity is the ideal protocol. Intravenous fluid and electrolyte therapy are administered continuously until recovery is apparent. Whole blood transfusions are used in calves and foals, especially when immunoglobulin deficiency is suspected from the history or is determined by measurement of serum immunoglobulins of blood (see Chapter 3 for details on measuring immunoglobulins using various tests). In one series on neonatal septicaemia in calves, in which E. coli accounted for 50% of the bacterial isolates, the survival rate was only 12%.

Enteric colibacillosis

The considerations for treatment of enteric colibacillosis include the following:
- Fluid and electrolyte replacement
- Antimicrobial and immunoglobulin therapy
- Antimotility drugs and intestinal protectants
- Alteration of the diet
- Clinical management of outbreaks.

**Fluid and electrolyte replacement**

The dehydration, acidosis and electrolyte imbalance are corrected by the parental and oral use of simple or balanced electrolyte solutions. The provision of fluid therapy in diarrheic dehydrated calves under field conditions in veterinary practice has been described. It is important to obtain an adequate history of the case including age of the calf, duration of the diarrhea and all treatments already given by the owner. The physical examination of the calf includes a standard clinical examination with emphasis on evaluating the degree of dehydration and acidosis.

**Dehydration** is evaluated by two clinical observations:
- **Skin elasticity.** The skin of the middle of the neck is better than the eyelid. A portion of the skin is tented and twisted for 1 second, and then the time to return to the initial position is measured – less than 2 seconds in the normal calf, 6 seconds in moderate (8%)
dehydration and more than 8 seconds in severe (12%) dehydration
- **Position of eyeball in the orbit and extent of enophthalmos.** This is determined by measuring the distance between the globe and the orbit. The eyeball is not sunken in healthy calves. Degrees of dehydration of 4%, 8%, and 12% are represented by a 2 mm, 4 mm, and 7 mm enophthalmos, respectively.

**Acidosis** can be evaluated using the clinical findings of mental status, muscular tone, ability to stand, intensity of the sucking reflex, temperature of the inside of the oral cavity, and age of the calf that correlates with an estimate of the base deficit. The following categories for diarrheic calves are being used under field conditions:

1. Calves with good muscular tone and the ability to stand, strong suck reflex and warm oral cavity have no base deficit if younger than 8 days of age, and up to 5 mEq/L if older than 5 days
2. Calves that can stand, have a slightly cool oral cavity and weak suck reflex have a base deficit of 5 mEq/L if under 8 days of age and 10 mEq/L if older than 8 days
3. Calves in sternal recumbency with a cool oral cavity and no suck reflex have a base deficit of 10 mEq/L if under 8 days of age and 15 mEq/L if older than 8 days
4. Calves in lateral recumbency that lack a suck reflex and have a cold oral cavity have a base deficit of 10 mEq/L if under 8 days of age and 20 mEq/L if older than 8 days.

Categorizing diarrheic calves into treatment groups

Based on the history and clinical findings, affected calves can be divided into categories according to the type of therapy required and which is most economical.

1. **Oral fluid therapy.** Calves with a history of acute diarrhea, less than 7% dehydrated, slightly dry oral mucosa, good suck reflex, good muscle tone, alert, able to stand and warm mouth. These can be treated with oral fluids and electrolytes

2. **Oral fluid therapy and hypertonic saline.** Calves with 7–9% dehydration and slight acidosis, weak suck reflex, good muscular tone, warm mouth. Administer hypertonic saline (7.5% NaCl) intravenously at 3–4 mL/kg BW in 5 minutes. Administer oral fluids and electrolytes by stomach tube at 40–60 mL/kg BW. Re-evaluate in 6–8 hours

3. **Intravenous fluid therapy with alkalinizing agents.** Calves are more than 9% dehydrated, dry and cool oral mucous membranes, reumbent, no suck reflex, very depressed. Provide intravenous replacement and maintenance fluid and electrolyte therapy for a period of 6–8 hours and up to 24–36 hours if necessary.

The details for parenteral and oral fluid and electrolyte therapy are described here.

**Parenteral fluid therapy**

In severe dehydration and acidosis, solutions containing the bicarbonate ion are indicated.

**Parenteral fluid composition**

An equal mixture of isotonic saline (0.85%), isotonic sodium bicarbonate (1.3%), and isotonic dextrose (5%) is a simple, effective solution for parenteral use. Sodium bicarbonate as an alkalinizing compound in the parenteral fluids is superior to the use of compounds such as sodium acetate or sodium lactate, which must be metabolized by the liver, myocardium, and other tissues in order to have an alkalinizing effect. The simple replacement of fluid losses using saline or fluids without alkalinizing compounds is likewise not as effective as sodium bicarbonate.

Many commercial preparations are effective in correcting the dehydration and electrolyte imbalances, but only those containing bicarbonate or its precursors are effective in correcting the metabolic acidosis. The bicarbonate requirements to treat acidosis are calculated using the equation:

\[
\text{weight (kg)} \times \text{base deficit (mMol/L)} \times 0.6 \text{ (extracellular fluid space)}.
\]

The base deficit will range from −5 to −20 mMol/L with an average of about −15 mMol/L. The bicarbonate requirements for a 45 kg calf with a base deficit of 15 mMol/L, are 45 × 15 × 0.6 = 405 mmol, which requires 37.75 g of sodium bicarbonate (1 g of sodium bicarbonate yields 12 mmol of bicarbonate), which can be delivered in 2.5 L of 1.3% isotonic solution. Diarrheic calves over 8 days of age may be nearly twice as acidic as younger calves and will require more bicarbonate to correct the acidosis. It is estimated that severely recumbent calves under 8 days of age require 1 L of isotonic sodium bicarbonate to correct the acidosis, in addition to the necessary amounts of saline to correct the dehydration; for calves over 8 days of age, 2 L of isotonic sodium bicarbonate is necessary. For laterally recumbent diarrheic calves under and over 8 days of age, 1 and 3 L, respectively, is required. Isotonic sodium bicarbonate is a safe solution intravenously; when the degree of acidosis is uncertain, up to several liters can be used safely for the correction of acidosis and volume depletion.

For severe dehydration (10–12% BW) fluids should be replaced as follows: hydration therapy 100 mL/kg BW intravenously in the first 1–2 hours at the rate of 50–80 mL/kg BW per hour followed by maintenance therapy at 140 mL/kg BW over the next 8–10 hours at the rate of about 20 mL/kg BW per hour. For example, a 45 kg calf that is 10% dehydrated should receive 4.5 L of fluid in the first 1–2 hours as hydration therapy, followed by 6–8 L of fluid over the next 8–10 hours. Initially, both the acidosis and the dehydration can be treated by the use of isotonic sodium bicarbonate followed by the use of a combined mixture of isotonic saline and isotonic sodium bicarbonate or multiple electrolyte solutions for maintenance therapy. For moderate dehydration (6–8% of BW), fluids should be replaced as follows: hydration therapy 50 mL/kg BW intravenously in the first 1–2 hours at the rate of 50–80 mL/kg BW per hour followed by maintenance therapy as described above.

Maintenance therapy may be provided using oral fluids and electrolytes if the calf is well enough to suck from a nipple bottle or drink from a pail. The use of solutions containing potassium chloride is sometimes recommended, on the basis that total potassium stores may be depleted in severely affected calves. However, they should be used with caution because a severe hyperkalemia may be present when there is a severe acidosis. If the acidosis and hypoglycemia are corrected with glucose and bicarbonate, the administration of potassium may be beneficial in restoring total potassium stores. However, solutions containing potassium can be cardiotoxic, especially if renal function is not restored.

**Hyperkalemia in the diarrheic calf**

Treatment of the acidosis and expanding plasma volume and increasing the serum sodium concentration will correct hyperkalemia in dehydrated diarrheic calves.

**Hypernatremia in the diarrheic calf**

The treatment of hypernatremia is difficult and unreliable. If there is a concurrent acidosis it should be treated with a bicarbonate solution. The objective is to decrease serum sodium concentration more slowly than is possible with traditional isotonic fluids. It is recommended that a sodium-containing fluid containing sodium equal to 95–100% of the animal’s serum sodium concentration, or with a fluid containing 170 mEq/L of sodium, be used initially. The animal’s serum sodium concentration is monitored so as not to
exceed a change of 0.3–0.5 mEq/h in serum sodium. Cerebral edema may be treated with mannitol.

**Acidosis without dehydration**

Some calves 10–20 days of age with a history of diarrhea in the previous several days may be affected with metabolic acidosis without obvious clinical evidence of dehydration. They are atactic, weak, sometimes recumbent, and may appear comatose. The intravenous administration of 2–3 L of isotonic (1.5%) sodium bicarbonate results in recovery within an hour.

**Hypertonic saline**

Because the administration of large quantities of isotonic fluids may be impractical in a farm situation because it requires long-term venous catheterization, appropriate restraint and periodic monitoring, the use of hypertonic saline has been explored as a rapid, inexpensive, effective method of fluid administration in severely dehydrated calves. 

Hypertonic saline (7.2% NaCl) solution and 6% Dextran 70 solution have been used successfully to resuscitate animals with hypovolemic endotoxic shock. Administration of 7.2% hypertonic saline and 6% Dextran 70 solution rapidly increases plasma volume, cardiac output and mean arterial pressure in hypovolemic and endotoxic shock. The hypertonic saline and Dextran 70 are given intravenously at a rate of 4–5 mL/kg BW over a period of 4 minutes followed by allowing the calf to suck an isotonic alkalinizing oral electrolyte solution at 50 mL/kg BW. Calves that do not suck are given the oral fluids by stomach tube. An additional dose of oral fluids at 50 mL/kg BW is given 12 hours later. This regime provides a rapid, practical, economical and effective method for the treatment of dehydrated diarrheic calves.

**Intravenous catheterization of calves**

Catheterization of the jugular vein is the most widely used approach for continuous long-term intravenous fluid therapy in calves. The jugular vein may be difficult to catheterize in severely dehydrated calves when the vein is collapsed and not visible even after prolonged occlusion. In addition, the tough and dry skin makes catheterization difficult. To increase the tension of the vein, calves may be raised by their pelvic limbs, thus increasing blood flow to the head and neck regions. An incision of the skin (a cut-down) makes placement of a catheter easier. A major advantage of jugular vein catheterization is the more rapid flow rate that is possible because 14-gauge catheters are commonly used.

Catheterization of the auricular veins in calves is becoming common, especially in Europe. Even in severely dehydrated calves, ear vein catheterization is successful. Ear catheters allow the application of sufficient amounts of fluids by continuous drip infusion and there are fewer complications compared to jugular vein catheters. In vitro flow rates for 22-gauge catheters range between 28 and 36 mL/min, providing an in vivo flow rate into the calf’s ear catheter of approximately 1.2–2.2 L/h.

**Oral fluid and electrolyte therapy**

Oral fluid and electrolyte therapy are indicated for calves in the early stages of diarrhea or after they have been successfully hydrated following parenteral fluid therapy. Severely dehydrated or moribund calves may not respond favorably to oral fluid therapy alone. Owners must be encouraged to provide oral fluid and electrolyte therapy to diarrheic neonatal farm animals as soon as possible after the onset of diarrhea. Almost all the information available on oral fluids has been developed following clinical studies in diarrheic calves, and the recommendations here reflect those studies.

In neonatal calves, the ideal oral electrolyte solution should: (a) supply sufficient sodium to facilitate normalization of extracellular fluid deficits; (b) provide two or more agents (such as glucose, acetate, propionate, or glycine) that facilitate intestinal absorption of sodium and water; (c) provide an alkalinizing agent (such as acetate, propionate, citrate, or bicarbonate) to treat the metabolic acidosis often present in dehydrated diarrheic calves; (d) not interfere with milk clotting in the abomasum; (e) provide sufficient energy, as these electrolyte solutions may be administered instead of milk or milk replacer for short periods of time; and (f) facilitate repair of damaged intestinal epithelium.

Acetate and propionate are the preferred alkalinizing agents for treating dehydrated calves with mild metabolic acidosis. Acetate and propionate have similar alkalinizing ability to bicarbonate on an equimolar basis, with the advantage that acetate and propionate produce energy. Acetate and propionate also stimulate sodium and water absorption in the calf's small intestine, but in the jejunum to a greater extent than the ileum. Acetate and propionate are readily metabolized by both fed and fasted calves. Moreover, acetate and propionate are metabolized by peripheral tissues, are not produced endogenously in shock and dehydration (as is lactate) and do not have an unmetabolized isomer (o-lactate). Finally, acetate and propionate do not alkalize the abomasum and intestine, whereas bicarbonate can permit bacteria to proliferate in an alkalinized abomasum, while also inhibiting the normal clotting of milk.

The ideal electrolyte concentration, osmolality and energy source for an oral electrolyte solution to treat neonatal calf diarrhea remain controversial. The optimal solution should have a sodium concentration between 60 and 120 mmol/L, a potassium concentration between 10 and 20 mmol/L, a chloride concentration between 40 and 80 mmol/L, 40–80 mmol/L of metabolizable (noncarbohydrate) base, such as acetate or propionate, and glucose as an energy source. Some investigators have suggested that the optimal oral electrolyte solution required a higher sodium concentration (120–133 mmol/L) to rapidly correct extracellular electrolyte and fluid losses that typically develop in calves with dehydration and diarrhea. Combined administration of sodium and glucose is beneficial because glucose facilitates sodium absorption via the small intestinal sodium/glucose co-transport mechanism.

Oral fluid and electrolyte therapy is effective in enteric colibacillosis of neonatal farm animals because glucose continues to be absorbed by the small intestine by an active transport mechanism accompanied by glucose-coupled sodium absorption and absorption of water. In enterotoxigenic colibacillosis, there is net hypersecretion caused by the enterotoxin, the intestinal mucosa is sufficiently intact so that water and sodium will be absorbed in the presence of glucose. Most oral electrolytes intended for the treatment of dehydration and acidosis in diarrheic calves contain sodium chloride and sodium bicarbonate with one or some of the following substances: glucose, acetates and citrates, phosphates, potassium salts, glycine and amino acids.

Several commercial oral preparations are available. The ideal solutions should be palatable and provide rapid rehydration and correction of acidosis. Diarrheic calves must receive sufficient fluid therapy to compensate for the fluid and electrolyte losses that occur and for maintenance and contemporary losses during the period of clinical diarrhea and convalescence. However, the calf must be returned to a milk diet within a few days in order to avoid the effects of malnutrition. Oral fluid and electrolyte formulas cannot provide the daily maintenance requirements of energy, protein, and fat. Some formulations contain a large quantity of glucose and are supplemented with glycine, sodium acetate, and citric acid, thus making a calorie-dense, partially nitrogen-balanced hyperosmolar solution. A glucose-containing oral rehydration solution for the treatment of experimental E. coli calf diarrhea was more effective in correcting and sustaining plasma, extracellular fluid, and blood volume compared with the standard saline solution.

To alkalinize the fluid the bicarbonate is mixed with the antacid (usually magnesium hydroxide) and administered as a suspension. The alkalinizing solution rapidly increases plasma volume, cardiac output and mean arterial pressure in hypovolemic and endotoxic shock. An additional dose of oral fluids at 50 mL/kg BW is given 12 hours later. This regime provides a rapid, practical, economical and effective method for the treatment of dehydrated diarrheic calves.
Diseases associated with *Escherichia coli*

Change in small intestinal bacterial flora in calves with diarrhea

There has been a paradigm shift in the last 40 years towards categorizing an episode of calf diarrhea as being due to a specific etiologic agent, such as rotavirus, coronavirus, *Salmonella* spp., or enterotoxigenic *E. coli*. While the etiologic approach has correctly focused attention on preventive programs, including vaccination and optimizing transfer of colostrum immunity, the approach has diverted attention from the universal finding of all studies, that calves with diarrhea have coliform bacterial overgrowth of the small intestine.\(^{25}\)

Studies completed more than 70 years ago documented increased numbers of *E. coli* bacteria in the abomasum, duodenum, and jejunum of scours calves. Moreover, calves severely affected with diarrhea had increased numbers of *E. coli* bacteria in the anterior portion of their intestinal tracts compared to mildly affected animals. More recent studies have consistently documented the fact that calves with naturally acquired diarrhea, regardless of age and the etiologic cause for the diarrhea, have altered small intestinal bacterial flora. Specifically, *E. coli* bacterial numbers are increased 5-10 000-fold in the duodenum, jejunum, and ileum of calves with naturally acquired diarrhea, even when the diarrhea was not due to enterotoxigenic strains of *E. coli*, and where rotavirus and coronavirus were identified in the feces. The largest increase in *E. coli* bacterial numbers occurs in the distal jejunum and ileum, whereas the *E. coli* or coliform bacterial numbers in the colon and feces are similar or higher for calves with diarrhea than calves without diarrhea, with *E. coli* being more numerous in the feces of colostrum-deprived than colostrum-fed calves. Small intestinal overgrowth with coliform bacteria can persist after departure of the initiating enteric pathogen.

Calves with naturally acquired diarrhea, increased small-intestinal colonization with *E. coli* has been associated with impaired glucose, xylose, and fat absorption.

Mixed infections with enteric pathogens are commonly diagnosed in calves with naturally acquired diarrhea, and the clinical signs and pathological damage associated with rotavirus infection are more severe when *E. coli* is present than when it is absent. Primary viral morphologic damage to the small intestine also facilitates systemic invasion by normal intestinal flora, including *E. coli*.

**Antimicrobial therapy**

Antimicrobials have been used extensively for the specific treatment of colibacillosis in calves and piglets because it was assumed that an infectious enteritis was present that had the potential of developing into a bacteremia or septicaemia. Some preparations consist of a single antimicrobial, while others are mixtures with or without absorbents, astringents, and electrolytes. They have been used on an empirical basis, since few randomized controlled trials have been conducted.

It has been difficult to evaluate the efficacy of antimicrobials for the treatment of enteric colibacillosis because of the complex nature of the interactive factors that affect the outcome in naturally occurring cases. These include the presence of mixed infections, the effects of whether or not milk is withheld from the diarrheic calves, the effects of the immune status of individual calves, the variable times after the onset of diarrhea when the drugs are given, the possible presence of antimicrobial resistance, and the effects of supportive treatment such as electrolyte and fluid therapy.

The literature on the use of antimicrobials in the treatment of calf diarrhea has been critically reviewed by Constable\(^{25}\) and the following discussion strongly reflects his review and his evidence-based recommendations for the use of antimicrobials to treat calf diarrhea.

Small intestinal overgrowth with coliform bacteria can persist after departure of the initiating enteric pathogen.

Calves with naturally acquired diarrhea, increased small-intestinal colonization with *E. coli* has been associated with impaired glucose, xylose, and fat absorption.

Mixed infections with enteric pathogens are commonly diagnosed in calves with naturally acquired diarrhea, and the clinical signs and pathological damage associated with rotavirus infection are more severe when *E. coli* is present than when it is absent. Primary viral morphologic damage to the small intestine also facilitates systemic invasion by normal intestinal flora, including *E. coli*.
In calves with experimentally induced enterotoxigenic E. coli diarrhea, colonization of the small intestine by E. coli has been associated with impaired glucose and lactose absorption, decreased serum glucose concentration and possibly increased susceptibility to cryptosporidial infection.

In summary, calves with diarrhea have increased coliform bacterial numbers in the small intestine, regardless of etiology, and this colonization is associated with altered small-intestinal function, morphological damage, and increased susceptibility to bacteremia. It therefore follows that administration of antimicrobials that decrease small intestinal coliform bacterial numbers in calves with diarrhea may prevent the development of bacteremia, decrease mortality, and decrease morphological damage to the small intestine, thereby facilitating digestion and absorption and increasing growth rate.

**Incidence of bacteremia in calves with diarrhea**

Calves with diarrhea are more likely to have failure of transfer of passive immunity or partial failure of transfer of passive immunity, and this group of calves, in turn, is more likely to be bacteremic. This is an additional reason that antimicrobials may be indicated in the treatment of calf diarrhea. Colostrum-deprived calves that subsequently developed diarrhea were frequently bacteremic, whereas bacteremia occurred much less frequently in colostrum-fed calves that developed diarrhea.

Based on field studies of diarrheic calves, it can be assumed that, on average, 30% of severely ill calves with diarrhea are bacteremic, that the risk of bacteremia is higher in calves with failure of transfer of passive immunity than in calves with adequate transfer of passive immunity, and that the risk of bacteremia is higher in calves 5 days of age or older. The frequency of bacteremia is sufficiently high that treatment of calves with diarrhea that are severely ill (as manifest by reduced suck reflex, > 6% dehydration, weakness, inability to stand or clinical depression) should include routine treatment against bacteremia, with emphasis on treating potential E. coli bacteremia. Veterinarians should also assume that 8–18% of diarrheic calves with adequate transfer of passive immunity and systemic illness are bacteremic.

The prevalence of bacteremia is sufficiently high in systemically ill calves that effective antimicrobial treatment for potential bacteremia should be routinely instituted, regardless of transfer of passive immunity status and treatment cost. Withholding an effective treatment for a life-threatening condition, such as bacteremia in calves with diarrhea, cannot be condoned on animal welfare grounds.

**Antimicrobial susceptibility of fecal Escherichia coli isolates**

The most important determinant of antimicrobial efficacy in calf diarrhea is obtaining an effective antimicrobial concentration against bacteria at the sites of infection (small intestine and blood). The results of fecal antimicrobial susceptibility testing have traditionally been used to guide treatment decisions; however, susceptibility testing in calf diarrhea probably has clinical relevance only when applied to fecal isolates of enterotoxigenic strains of E. coli or pathogenic Salmonella spp., and blood culture isolates from calves with bacteremia. Validation of susceptibility testing as being predictive of treatment outcome for calves with diarrhea is currently lacking.

The ability of fecal bacterial culture and antimicrobial susceptibility testing using the Kirby Bauer technique to guide treatment in calf diarrhea is questionable when applied to fecal E. coli isolates that have not been identified as enterotoxigenic. There do not appear to be any data demonstrating that fecal bacterial flora is representative of the bacterial flora of the small intestine, which is the physiologically important site of infection in calf diarrhea. Marked changes in small-intestinal bacterial populations can occur without changes in fecal bacterial populations, and the predominant strain of E. coli in the feces of a diarrheic calf can change several times during the diarrhea episode. Furthermore, and most importantly, 45% of calves with diarrhea had different strains of E. coli isolated from the upper and lower small intestine, indicating that fecal E. coli strains are not always representative of small-intestinal E. coli strains.

An additional bias present in most antimicrobial susceptibility studies conducted on fecal E. coli isolates is that data are frequently obtained from dead calves, which are likely to be treatment failures. The time since death is also likely to be an important determinant of the value of fecal culture, because such a rapid proliferation of bacteria occurs in the alimentary tract after death that the results of examinations made on dead calves received at the laboratory can have little significance. Calves that die from diarrhea are likely to have received multiple antimicrobial treatments, and preferential growth of antimicrobial-resistant E. coli strains starts within 3 hours of antimicrobial administration. A further concern with fecal susceptibility testing is that the Kirby Bauer breakpoints (minimum inhibitory concentration (MIC)) are not based on typical antimicrobial concentrations in the small intestine and blood of calves. What are urgently needed are studies documenting the antimicrobial susceptibility of E. coli isolates from the small intestine of untreated calves, based on achievable drug concentrations and dosage regimens. Until these data are available, it appears that antimicrobial efficacy is best evaluated by the clinical response to treatment, rather than the results of in vitro antimicrobial susceptibility testing performed on fecal E. coli isolates.

A comparison of antibiotic resistance for E. coli populations isolated from groups of diarrheic and control calves in the UK found a higher incidence of antibiotic-resistant E. coli in samples obtained from farms with calf diarrhea than from farms without the disease. Considering all samples, bacterial colonies in 84% were resistant to ampicillin, in 13% to apramycin and in 6% to nalidixic acid. Antibiotic resistance among enterotoxigenic E. coli from piglets and calves with diarrhea in a diagnostic laboratory survey of one geographic area in Canada over a 13-year period found that least resistance occurred against cephalothin for all, followed by apramycin and gentamicin for porcin and florfenicol for bovine isolates.

Passive surveillance for antimicrobial resistance in E. coli isolates from diarrheic food animals continues to indicate that resistance to many of the common antimicrobials is increasing. In a UK study over a 5-year period, E. coli isolates from calves with diarrhea become more resistant to furazolidone, trimethoprim-potentiated sulfonamide, clavulanic-acid-potentiated amoxicillin, and tetracycline. E. coli strains from outbreaks of diarrhea in lambs in Spain became increasingly resistant to nalidixic acid, enoxacin, and enrofloxacin on the basis of the National Committee on Clinical Laboratory Standards (NCCL) breakpoints for human and animal isolates. Among the fluoroquinolones used for treatment of domestic animals in Spain, enrofloxacin is approved for use for the treatment of colibacillosis and diarrhea in lambs. However, the bovine and ovine strains of E. coli that possess potential virulence factors were more sensitive to quinolones than those that do not express these factors. Some antimicrobial-resistant E. coli strains from diarrheic calves in the USA may possess a chromosomal flo gene that specifies cross-resistance to both florfenicol and chloramphenicol, and its presence among E. coli isolates of diverse genetic backgrounds indicates a distribution much wider than previously thought. In Spain, 5.9% of E. coli strains from cattle were resistant to nalidixic acid and 4.9% were resistant to enrofloxacin and ciprofloxacin. In sheep and goats only 0.5% and 1.4%, respectively, of the strains were resistant to nalidixic acid.
to nalidixic acid and none to fluoroquinolones. Most of the quinolone-resistant strains were nonpathogenic strains isolated from cattle.

The CTX-M-14-like enzyme has been detected in E. coli recovered from the feces of diarrheic dairy calves in Wales. The enzyme is an extended-spectrum beta-lactamase (ESBL), which confers resistance to a wide range of beta-lactam (penicillin and cephalosporin) compounds. Organisms possessing ESBLs are considered to be resistant to second-, third-, and fourth-generation cephalosporins, and in vitro resistance to amoxicillin/clavulanate among producers is variable, reflecting the amount of beta-lactamase produced. In addition to this enzyme, the isolates produced a TEM-35 (IRT-4) beta-lactamase that conferred resistance to the amoxicillin/clavulanate combination. These two enzymes confer resistance to all the beta-lactamase compounds approved for veterinary use in the UK. Thus their occurrence in animals may be an important development for both animal and public health. ESBLs in human infections have emerged as a significant and developing problem, occurring in patients in the community as well as in those with recent hospital contact. Spread of this form of resistance in bacteria affecting the animal population could have serious implications for animal health, rendering many therapeutic options redundant.

Antibiotic resistance to intestinal bacteria also occurs in dairy calves fed milk from cows treated with antibiotics. The resistance increases with higher concentrations of antibiotics in the milk.

Antimicrobial susceptibility of blood Escherichia coli isolates

The Kirby Bauer technique for antimicrobial susceptibility testing has more clinical relevance for predicting the clinical response to antimicrobial treatment when applied to blood isolates rather than fecal isolates. This is because the Kirby Bauer breakpoints (MICs) are based on achievable antimicrobial concentrations in human plasma and MIC90 values for human E. coli isolates, which provide a reasonable approximation to achievable MIC values in calf plasma and MIC90 values for bovine E. coli isolates. Unfortunately, susceptibility results are not available for at least 48 hours, and very few studies have documented the antimicrobial susceptibility of blood isolates in calves with diarrhea. In a 1997 study of dairy calves in California, the antimicrobial susceptibility of isolates from the blood of calves with severe diarrhea or illness produced the following results: ceftiofur, 19/25 (76%) sensitive; potentiated sulfonamides, 14/25 (56%) sensitive; gentamicin, 12/25 (48%) sensitive; ampicillin, 11/25 (44%) sensitive; tetracycline, 3/25 (12%) sensitive, although there was a clinically significant year-to-year difference in the results of susceptibility testing that may have reflected different antimicrobial administration protocols on the farm.

Evidence-based recommendations for antimicrobial treatment of diarrheic calves

The four critical measures of success of antimicrobial therapy in calf diarrhea are (in decreasing order of importance): (1) mortality rate, (2) growth rate in survivors, (3) severity of diarrhea in survivors, and (4) duration of diarrhea in survivors. Success of antimicrobial therapy can vary with the route of administration and whether the antimicrobial is dissolved in milk, oral electrolyte solutions, or water. Oral antimicrobials administered as a bolus or contained in a gelatin capsule are deposited into the rumen and therefore have a different serum concentration–time profile from antimicrobials dissolved in milk replacer that are sucked by the calf or administered as an oral drench at the back of the pharynx. Antimicrobials that bypass the rumen are not thought to alter rumen microflora, potentially permitting bacterial recolonization of the small intestine from the rumen. Finally, when oral antimicrobials are administered to calves with diarrhea, the antimicrobial concentration in the lumen of the small intestine is lower and the rate of antimicrobial elimination faster than in healthy calves. Orally administered amoxicillin, chlorotetracycline, neomycin, oxytetracycline, streptomycin, sulfachloropyridazine, sulfamethazine, and tetracycline are currently labeled for the treatment of calf diarrhea. Unfortunately, there is little published data supporting their efficacy in treating calves with diarrhea. Extralabel antimicrobial use (excluding prohibited antimicrobials) is therefore justified in treating calf diarrhea because of the apparent lack of published studies documenting clinical efficacy of antimicrobials with a label claim, and because the health of the animal is threatened and suffering or death may result from failure to treat systemically ill calves.

Because the two sites of infection in calf diarrhea are the small intestine and blood, administered antimicrobials should have both local (small intestinal) and systemic effects. In addition, the antimicrobial must reach therapeutic concentrations in the site of infection for a long enough period and, ideally, have only a narrow Gram-negative spectrum of activity in order to minimize collateral damage to other enteric bacteria. In general, oral and parenteral administration of broad-spectrum beta-lactam and fluoroquinolone antimicrobials have proven efficacy in treating naturally acquired and experimentally induced diarrhea, parenteral administration of trimethoprim-sulfadiazine has proven efficacy in treating experimentally induced Salmonella enterica serotype Dublin (although efficacy has only been demonstrated when antimicrobial administration starts before diarrhea is present), and oral administration of the predominantly Gram-negative-spectrum.
amicrobial apramycin has proven efficacy in treating naturally acquired diarrhea. Because use of fluoroquinolone antimicrobials in an extralabel manner is illegal in the USA, and apramycin is an aminocyclitol antimicrobial that is poorly absorbed after oral administration (oral bioavailability <15%) and has relatively high MIC values against Salmonella spp. and E. coli (MIC \(_{90} > 3 \mu g/mL\)) in the calf, treatment recommendations will focus on the use of broad-spectrum beta-lactam antimicrobials such as amoxicillin, ampicillin, ceftiofur, and potentiated sulfonamides (trimethoprim– sulfadiazine).

**Administration of oral antimicrobials to treat Escherichia coli overgrowth of the small intestine**

Based on published evidence for the oral administration of these antimicrobial agents, only amoxicillin can be recommended for the treatment of diarrhea; dosage recommendations are amoxicillin trihydrate (10 mg/kg every 12 h) or amoxicillin trihydrate–clavulanic acid at 12.5 mg/kg every 12 h for at least 3 days, the latter constitutes extralabel drug use. Parenteral administration of broad-spectrum beta-lactam antimicrobials (ceftiofur, 2.2 mg/kg intramuscularly or subcutaneously every 12 h; amoxicillin or ampicillin, 10 mg/kg intramuscularly every 12 h) or potentiated sulfonamides (25 mg/kg intravenously or intramuscularly every 12 h) is recommended for treating calves with diarrhea and systemic illness; both constitute extralabel drug use.

Concurrent feeding of milk and amoxicillin does not change the bioavailability of amoxicillin, although amoxicillin is absorbed faster when dissolved in an oral electrolyte solution than in milk replacer and absorption is slowed during endotoxemia, presumably because of a decrease in abomasal emptying rate. Amoxicillin trihydrate is preferred to ampicillin trihydrate for oral administration in calves because it is labeled for the treatment of calf diarrhea in the USA and is absorbed to a much greater extent. However, a field study comparing oral amoxicillin (400 mg every 12 h) and ampicillin (400 mg every 12 h) treatments for diarrhea reported similar proportions of calves with a good to excellent clinical response (79%, 49/62 for amoxicillin bolus; 80%, 59/74 for amoxicillin powder; 65%, 47/75 for ampicillin bolus, \(p > 0.30\) for all comparisons). The addition of clavulanic acid to amoxicillin trihydrate is recommended because clavulanic acid is a potent irreversible inhibitor of beta-lactamase, increasing the antimicrobial spectrum of activity.

Sulbactam/ampicillin was effective for the treatment of experimentally induced diarrhea in calves infected with *E. coli* strain B44 (O9:K30:K99H). The survival rate in treated calves was 100% compared to 22% in control calves treated only with saline. Cefotiofur hydrochloride—a broad-spectrum, beta-lactamase-resistant cephalosporin—at an oral dose of 10 mg/kg BW given once was effective for the treatment of experimentally induced enteric colibacillosis in piglets.

Oral administration of potentiated sulfonamides is not recommended for treating calf diarrhea because of the lack of efficacy studies. Gentamicin (50 mg/calf orally every 12 h) markedly decreased *E. coli* bacterial concentrations in the feces of healthy calves and treatment with gentamicin has improved stool consistency in calves with experimentally induced *E. coli* diarrhea. However, oral administration of gentamicin is not recommended, because antimicrobials administered to calves with diarrhea should have both local and systemic effects, and orally administered gentamicin is poorly absorbed.

Fluoroquinolones clearly have proven efficacy in treating calf diarrhea and a label indication exists in Europe for oral administration of ceftiofur to treat enteric colibacillosis in pigs. This antimicrobial is resistant to the action of beta-lactamase, the MIC\(_{90}\) for *E. coli* is less than 0.25 \(\mu g/mL\); the recommended dosage schedule maintains free plasma beta-lactam antimicrobial concentrations at the desired four times above the MIC\(_{90}\) for the duration of treatment in 7-day-old calves, and 30% of the active metabolite of ceftiofur (desurirofloxacin) is excreted into the intestinal tract of cattle, providing antimicrobial activity in both blood and small intestine. Moreover, parenteral (2 mg/kg, intramuscularly once) or oral (0.5 mg/kg, once) administration of fluoroquinolone class of antimicrobials in food-producing animals in the US is illegal to use some of the antimicrobials which makes examination of the animals for bacteremia and diarrhea in pigs was attributed to decreasing intestinal luminal concentration of pathogenic *E. coli*. Orally administered ceftiofur sodium (≤5 mg/kg daily) was also effective in treating mice with experimentally induced enteric colibacillosis. Administration of ceftiofur to treat bacteremia and diarrhea in calves is contraindicated extralabel drug use, and ceftiofur should not be administered to calves to be processed as veal.

Another recommended treatment is parental amoxicillin trihydrate or ampicillin trihydrate (10 mg/kg intramuscularly every 12 h) for at least 3 days. Although parental ampicillin has proven efficacy in treating naturally acquired diarrhea whereas ceftiofur has proven efficacy, the broad-spectrum beta-lactam antimicrobials amoxicillin and ampicillin are theoretically inferior to ceftiofur because parenterally administered ampicillin and amoxicillin reach lower plasma concentrations and require a higher MIC than ceftiofur, and are not beta-lactamase-resistant. Amoxicillin or ampicillin should be injected into the neck muscle because this site provides the greatest absorption and minimizes damage to the clinician monitors the health of calves with experimentally induced enteric colibacillosis, although these pigs were not suspected to be bacteremic.

The beneficial effects of parental ceftiofur in pigs was attributed to decreasing intestinal luminal concentration of pathogenic *E. coli*. Orally administered ceftiofur sodium (≤5 mg/kg daily) was also effective in treating mice with experimentally induced enteric colibacillosis. Administration of ceftiofur to treat bacteremia and diarrhea in calves constitutes extralabel drug use, and ceftiofur should not be administered to calves to be processed as veal.

**Administration of parenteral antimicrobials to treat Escherichia coli bacteremia**

In calves with diarrhea and moderate to severe systemic illness, the positive predictive value (0.65) of clinical tests (sensitivity = 0.39, specificity = 0.91) and the positive predictive value (0.77) of laboratory tests (sensitivity = 0.40, specificity = 0.95) for detecting bacteremia are too low assuming reasonable estimates for the prevalence of bacteremia (30%). Accordingly, it is recommended that clinicians routinely assume 30% of all calves with diarrhea are bacteremic, and that bacteremia constitutes a threat to the life of the calf.

The most logical parenteral treatment is ceftiofur (2.2 mg/kg intramuscularly/subcutaneously every 12 h) for at least 3 days. Cefotiofur is the most appropriate antimicrobial because it is a broad-spectrum beta-lactam antimicrobial that is resistant to the action of beta-lactamase, the MIC\(_{90}\) for *E. coli* is less than 0.25 \(\mu g/mL\), the recommended dosage schedule maintains free plasma beta-lactam antimicrobial concentrations at the desired four times above the MIC\(_{90}\) for the duration of treatment in 7-day-old calves, and 30% of the active metabolite of ceftiofur (desurirofloxacin) is excreted into the intestinal tract of cattle, providing antimicrobial activity in both blood and small intestine. Moreover, parenteral (2 mg/kg, intramuscularly once) or oral (0.5 mg/kg, once) administration of fluoroquinolone class of antimicrobials in food-producing animals in the US is illegal to use some of the antimicrobials which makes examination of the animals for bacteremia and diarrhea in pigs was attributed to decreasing intestinal luminal concentration of pathogenic *E. coli*. Orally administered ceftiofur sodium (≤5 mg/kg daily) was also effective in treating mice with experimentally induced enteric colibacillosis. Administration of ceftiofur to treat bacteremia and diarrhea in calves is contraindicated extralabel drug use, and ceftiofur should not be administered to calves to be processed as veal.
more valuable areas of the carcass. Amoxicillin and ampicillin should not be administered subcutaneously, as the rate and extent of absorption is reduced relative to intramuscular injection.

A third recommended treatment is parenteral potentiated sulfonamides (20 mg/kg sulfadiazine with 5 mg/kg trimethoprim, intravenously or intramuscularly according to formulation characteristics, every 24 h for 5 d). The efficacy of potentiated sulfonamides has only been proved when treatment commenced before clinical signs of diarrhea were present. It is therefore unknown whether potentiated sulfonamides are efficacious when administered to calves with diarrhea and depression, although it is likely that potentiated sulfonamides are efficacious in the treatment of salmonellosis.

Oral administration of potentiated sulfonamides and apramycin is not recommended for the treatment of bacteremia, because of poor oral bioavailability. Oxytetracycline or chlorotetracycline are also not recommended for the treatment of bacteremia, although tetracyclines may have some efficacy for treating E. coli bacteremia in the small intestine. Tetracycline antimicrobials are bound to calcium, and oral bioavailability when administered with milk is 46% for oxytetracycline and 24% for chlorotetracycline.

Parenteral administration of gentamicin and other aminoglycosides (amikacin, kanamycin) cannot currently be recommended as part of the treatment for calf diarrhea because of the lack of published efficacy studies, prolonged slaughter withdrawal times (15–18 months), potential for nephrotoxicity in dehydrated animals, and availability of ceftiofur, amoxicillin, and ampicillin.

A label indication exists in Europe for parenteral enrofloxacin in the treatment of calf diarrhea. In those countries where administration is permitted to treat calves with diarrhea, parenteral fluoroquinolones are recommended because of their broad-spectrum bactericidal activity, particularly against Gram-negative bacteria. However, it must be emphasized that extra-label use of the fluoroquinolone class of antimicrobials in food-producing animals in the USA is illegal and obviously not recommended.

Chloramphenicol has proven efficacy in treating calf diarrhea due to Salmonella enterica serotypes Bredeney and Dublin, although its use is now illegal in the USA. The related antimicrobial florfenicol achieves high concentrations in the lumen of the small intestine and is 89% absorbed when orally administered to milk-fed calves; however, florfenicol does not provide the most appropriate antimicrobial for treating calf diarrhea, as the MIC90 for E. coli is very high at 25 μg/mL and florfenicol (11 mg/kg orally or 20 mg/kg intramuscularly) failed to reach the MIC90 value in plasma, whereas florfenicol (11–20 mg/kg intravenously) only exceeded the MIC90 value for less than 60 minutes.

In calves with diarrhea and no systemic illness (normal appetite for milk or milk replacer, no fever), we recommend that the clinician monitors the health of the calf and does not administer parenteral antimicrobials.

**Immunoglobulin therapy**

One of the important factors determining whether or not calves survive enteric colibacillosis is the serum immunoglobulin status of the animal before it develops the disease. The prognosis is unfavorable if the level of immunoglobulins is low at the onset of diarrhea, regardless of intensive fluid and antimicrobial therapy. Most of the literature on therapy omits this information and is therefore difficult to assess. There is ample evidence that the mortality rate will be high in diarrheic calves that are deficient in serum immunoglobulins, particularly IgG, in spite of exhaustive antimicrobial and fluid therapy. This has stimulated interest in the possible use of purified solutions of bovine gammaglobulin in diarrheic calves that are hypogammaglobulinemic. However, they must be given by the intravenous route and in large amounts, the cost of which would be prohibitive. In addition, they are unlikely to be of value once the calf is affected with diarrhea; they are protective and probably not curative. Whole blood transfusion to severely affected calves may be used as a source of gammaglobulins but unless given in large quantities would not significantly elevate serum immunoglobulin levels in deficient calves. Limited controlled trials indicate that there is no significant difference in the survival rate of diarrheic calves treated with either a blood transfusion daily for 3 days, fluid therapy given orally, subcutaneously, or intravenously depending on the severity of the dehydration; or fluid therapy with antibiotics. Those calves that survived, regardless of the type of therapy, had high levels of immunoglobulins before they developed diarrhea. This emphasizes the importance of the calf ingesting liberal quantities of colostrum within the first few hours after birth.

**Antimotility drugs and intestinal protectants**

There is no good evidence that antimotility drugs are of any therapeutic value for the treatment of enteric colibacillosis. Intestinal protectants such as kaolin and pectin are in general use for diarrheic animals but likewise their value is uncertain. When they are used the feces become bulky but do not have any known effect on the pathogenesis of the disease.

**Alteration of the diet**

Whether or not diarrheic newborn animals should be deprived of milk during the period of diarrhea is controversial. Diarrheic piglets are usually treated with an antimicrobial orally and left to nurse on the sow. Diarrheic beef calves are commonly treated with oral fluids and electrolytes and left with the cow. However, it is a common practice to reduce the milk intake of diarrheic hand-fed calves for up to 24 hours or until there is clinical evidence of improvement. The withholding of milk from diarrheic calves has been based on the observations that lactose digestion is impaired and that 'resting' the intestine for a few days minimizes additional osmotic diarrhea caused by fermentation of undigested lactose in the large intestine. Thus it has seemed logical not to feed the animal with milk, which must be digested, but rather to provide readily absorbable substances such as oral glucose-electrolyte mixtures. In contrast, the argument in favor of continuous feeding of milk is that the intestinal tract requires a constant source of nutrition, which it receives from the ingesta in the lumen of the intestine. It has also been proposed that starvation diarrheic calves from milk can result in malnutrition, suboptimal growth rates, and prolonged recovery. In one study it was shown that the offering of milk to diarrheic calves when they were willing to drink following hydration therapy in a clinic resulted in a higher but insignificant improvement in survival rate than in calves that were starved from milk for 24 hours. In another study, the continued feeding of cows’ whole milk and fluids and electrolytes to experimentally induced diarrheic calves sustained the growth rate of the animals over the trial period of 10 days even though the diarrhea persisted. The use of whole milk and oral rehydration solutions for calves with naturally occurring diarrhea did not prolong the diarrhea or make it worse but the calves were in the early stages of diarrhea and were neither severely dehydrated nor acidotic.

It has been common practice to use oral fluids and electrolytes as milk replacement during the period of diarrhea. Such mixtures are inexpensive, easy to use, readily available and, if used by the farmer when diarrhea is first noticed, will usually successfully treat existing dehydration and prevent further dehydration and acidosis.
Following recovery, calves should be offered reduced quantities of whole milk three times daily (no more than total daily intake equivalent to 8% BW) on the first day and increased to the normal daily allowance in the next few days. Milk should not be diluted with water as this may interfere with the clotting mechanism in the abomasum.

Clinical management of outbreaks
The following principles should be considered when outbreaks of colibacillosis in neonatal farm animals are encountered:

- The veterinarian should visit the farm and conduct an epidemiological investigation to identify risk factors.
- Examine each risk factor and how it can be minimized.
- Examine affected animals.
- Identify and isolate all affected animals if possible.
- Treat all affected animals as necessary.
- Take laboratory samples from affected and normal animals.
- Make recommendations for the control of diarrhea in animals to be born in the near future.
- Prepare and submit a report to the owner describing the clinical and laboratory results and how the disease can be prevented in the future.

Health and welfare of calves
A survey of calf health and welfare on dairy farms in England examined the degree of compliance with the Welfare of Farmed Animals Regulations. The level of veterinary involvement in calf rearing and management on dairy farms was also assessed by questionnaire sent to large-animal practitioners. Compliance with the regulations was variable. The requirements for isolation of sick calves, provision of bovine colostrum within 6 hours after birth, provision of fresh, clean water and restrictions concerning tethering were not well complied with. However, the requirements for twice-daily feeding and inspection, visual and tactile contact between calves, access to forage and the provision of clean, dry bedding were well complied with. The results also suggested that there was some lack of veterinary input into the health and welfare of calves on dairy farms visited by the practices routinely and nonroutinely. These results suggest that there are considerable opportunities to improve calf health and management practices by veterinarians who visit dairy farms. This can be done through animal health management advice provided during routine visits to the farm and encouraging compliance with current welfare regulations and through the use of herd health plans. The major challenge for the veterinarian is to be able to communicate with owners and animal attendants about the care being provided to clinically ill neonates to insure that they are being treated according to their needs and made comfortable during their convalescence.

CONTROL
Because of the complex nature of the disease, it is unrealistic to expect total prevention, and control at an economical degree should be the major goal. Effective control of colibacillosis can be accomplished by the application of three principles:

- Reduction of the degree of exposure of the newborn to the infectious agents.
- Provision of maximum nonspecific resistance with adequate colostrum and optimum animal management.
- Increasing the specific resistance of the newborn by vaccination of the dam or the newborn.

Reduction of the degree of exposure of the newborn to the infectious agents
The emphasis is on insuring that the newborn are born into a clean environment. Barns, confinement pens, and paddocks used as parturition areas must be clean and should preferably have been left vacant for several days before the pregnant dams are placed in them.

Dairy calves
These comments are directed particularly at calves born indoors, where contamination is higher than outdoors.

- Calves should be born in well-bedded box stalls that were previously cleaned out.
- The perineum and udder of the dairy cow should be washed shortly before calving.
- Immediately after birth the umbilicus of the calf should be swabbed with 2% iodine. Tying the umbilicus at the level of the abdominal wall with cotton thread is also practiced.
- Calves affected with diarrhea should be removed from the main calf barn if possible and treated in isolation.

Beef calves
These are usually born on pasture or on confined calving grounds.

- Calving grounds should have been free of animals previous to the calving period; the grounds should be well drained, dry and scraped free of snow if possible. Each cow–calf pair should be provided with at least 2000 square feet of space. Calving on pasture with adequate protection from wind is ideal. Covering the calving grounds with straw or wood shavings provides a comfortable calving environment.
- In large beef herds, in a few days following birth when the calf is nursing successfully, the cow–calf pair should be moved to a nursery pasture to avoid overcrowding in the calving grounds.

In beef herds, breeding plans should insure that heifers calve at least 2 weeks before the mature cows. Limiting the breeding and therefore the calving season to 45 days or less for heifers also offers several advantages. A short calving season allows the producer to more effectively and economically concentrate personnel resources to the calving management compared to a longer calving season. Calving heifers earlier allows them additional time required before the next breeding season to be on an increasing plane of nutrition necessary to maintain a high conception rate. The earlier calving of heifers also provides less exposure of their calves to infection pressure from the mature animals in the herd.

The incidence and severity of neonatal disease will typically increase, and the age at disease onset will decrease as the calving season progresses. This phenomenon is common in beef herds because of the effect of the calf as a biological amplifier. The more the calving season is shortened, the more the biological amplification effect is negated.

For beef herds, it is necessary to have a plan for cattle movement throughout the calving season. This requires a minimum of four or five separate pastures. These include a gestation pasture, a calving pasture and a series of nursery pastures. To ensure that beef calves are born in a sanitary environment, the herd should be moved from the gestation pasture to the calving pasture 1–2 weeks before calving. One day after birth, the cow or heifer and her calf should be moved to a nursery pasture. Cow–calf pairs should be added to a single nursery pasture until the appropriate number of pairs has been reached. Thereafter, cow–calf pairs can be added to a second nursery pasture. The difference in age between the oldest and youngest calf in a nursery pasture should never exceed 30 days, and smaller differences are preferable. This negates the biological amplification effect. The longer the calving season, the greater the need for a larger number of nursery pastures. Calves that develop diarrhea should be removed immediately to an area away from healthy calves, treated and not returned until all calves in the group are at low risk for developing diarrhea (> 30 days of age).

The nutrition of the pregnant cows, and particularly the first-calf heifers, must
Diseases associated with *Escherichia coli*

**Quality of colostrum**

*Specific gravity*

Differentiating high-immunoglobulin-concentration colostrum from low-immunoglobulin-concentration is problematic. Measurement of the specific gravity of the colostrum of dairy cows with a commercially available hydrometer (Colostrometer) has been explored. Originally it was claimed that measurement of specific gravity provided an inexpensive and practical method for estimating colostral Ig concentration. However, the specific gravity of colostrum is more correlated with its protein concentration than Ig concentration and varies with colostral temperature, thus limiting the predictive accuracy of the test. In addition, different relationships between specific gravity and Ig concentration of colostrum have been observed for different populations of Holstein and Jersey cows and between herds. Specific gravity may also vary considerably according to season of the year. Specific gravity was measured in 1085 first-milking colostrum samples from 608 dairy cows of four breeds on a single farm during a 5-year period. The specific gravity more closely reflected protein concentration than IgG concentration and was markedly affected by month of calving. Colostral specific gravity values were highest for Holstein and Jersey cows, cows in third or later lactation and cows calving in autumn. They were lowest in Brown Swiss and Ayrshire cows, cows in first or second lactation, and cows calving in summer. Thus using the specific gravity of colostrum...
as an indicator of IgG concentration has potential limitations.

**Frozen and thawed colostrum**

Colostrum can be ranked as frozen colostrum for future use. Excess colostrum can be stored frozen and thawed as necessary to provide an IgG source when administration of dam colostrum is impractical or insufficient. Experience has shown that the composition of frozen colostrum remains constant throughout storage. No significant changes in pH, percentage acidity, milk fat, total solids, total nitrogen, or nonprotein resulted from colostrum being stored. Feeding 4 L of frozen thawed colostrum (which had been frozen at -20°C for 24 h) to calves by orosophageal tube at 3 hours after birth did not result in a significant difference in IgG absorption when compared to calves receiving fresh colostrum.87

**Pasteurization of colostrum**

Several infectious diseases of cattle can be transmitted from the dam to the calf through colostrum contaminated by direct shedding from the mammary gland or postharvest contamination. These diseases include Johne’s disease, bovine leukosis, Mycoplasma spp., Salmonella spp., and E. coli. Strategies to control transmission of infectious agents to calves include pasteurizing colostrum. Pasteurization is effective in destroying Mycoplasma bovis, Mycoplasma californicum, and Mycoplasma canadense if an adequate temperature and time are used.

The method of pasteurization of colostrum affects its quality for calves. The potential disadvantage of heat-treating colostrum is that the immunoglobulins may become denatured. Pasteurization at 76°C for 15 minutes results in a marked decrease in calf serum IgG concentrations, a severe failure of transfer of passive immunity, indicating that the colostral immunoglobulins were either destroyed or altered so that absorption was impaired. Pasteurization at 76°C for 15 minutes destroys or alters collostral proteins and affects the serum concentration of lactoferrin and neutrophil oxidative metabolism.88 Pasteurization of colostrum at 63°C for 15 minutes causes only negligible decreases in colostral IgG concentrations when fed to calves.89 However, these lower temperatures are less effective in the destruction of Mycobacterium avium subsp. paratuberculosis and other infectious agents transmitted through colostrum.

The effect of commercial on-farm batch pasteurization on colostrum IgG concentrations, fluid characteristics and serum IgG concentrations in calves fed fresh versus pasteurized colostrum have been compared.90 Pasteurization of moderately sized batches (57 L) using a commercial batch pasteurizer consistently produces a product of normal or slightly thickened consistency that can be fed to calves. Batch pasteurization of 57 L at 63°C for 30 minutes results in a significant reduction of IgG in colostrum (26%) but much less than when 95 L is pasteurized. The percentage loss of IgG is significantly reduced when starting with high-quality fresh colostrum (> 60 mg/L). Feeding pasteurized colostrum results in significantly lower serum IgG concentrations in calves. However, acceptable serum IgG levels can be achieved if the pasteurized colostrum is fed immediately after birth, if at least 4 L is fed and if the interval between the first and second feedings of colostrum is shortened.

Colostrum supplements and replacers Some colostrum-derived oral supplements containing immunoglobulin are available for newborn calves in which colostrum intake is suspected or known to be inadequate. **Colostrum supplement** products have been developed to provide exogenous IgG to calves when the dam’s fresh colostrum is of low IgG concentration. Many producers also use these products to replace colostrum when it is unavailable as a result of maternal agalactia, acute mastitis or other causes of inadequate colostrum supply. However, they contain low immunoglobulin concentrations compared to those found in high-quality first-milking colostrum. Most colostral supplements provide only 25-45 g IgG/dose of 454 g, which is reconstituted in 2 L of water. Feeding one or even two doses of such supplements is insufficient to provide a mass of 100 g of IgG within the first 12 hours after birth.

**Colostrum replacers** are intended to provide the sole source of IgG and thus must provide at least 100 g IgG. Newborn colostrum-deprived dairy calves fed spray-dried colostrum containing 126 g of immunoglobulin in 3 L of water as their sole source of Ig achieved normal mean serum immunoglobulin concentrations.91 Wheny protein concentrate as a colostrum substitute, administered to calves as a single feeding, was ineffective in preventing neonatal morbidity and mortality compared with a single feeding of pooled colostrum.92

The IgG derived from bovine serum or Ig concentrates from bovine plasma are well absorbed by neonatal calves when given in adequate amounts.9394 The serum concentration of IgG in calves at 2 days of age force-fed a colostrum supplement containing spray-dried serum (total of 90 g immunoglobulin protein) within 3 hours after birth was much lower than in calves fed 4 L of fresh colostrum.95 The mass of IgG and the method of processing are critical. Products providing less than 100 g of IgG/dose should not be used to replace colostrum.

To be successful, colostral supplements and replacers must provide enough IgG mass, which results in 24-hour calf serum IgG concentrations of more than 10 g/L.

**Purified bovine immunoglobulin**

The administration of purified bovine gammaglobulin to calves that are deficient appears to be a logical approach but the results have been unsuccessful. Large doses (30-50 g) of gammaglobulin given intravenously would be required to increase the level of serum gammaglobulin from 0.5 g/dL to 1.5 g/dL of serum, which is considered adequate to improve immune responses.96

**To be effective, infusion of immunoglobulin derived from blood must increase serum IgG concentrations and reduce morbidity and mortality prior to weaning without affecting later production. Parenteral infusions of immunoglobulins will increase the concentrations of serum IgG in calves but may not necessarily have an effect on morbidity or mortality.96 High levels of specific circulating Ig can serve as a reservoir of antibody to move into the intestine and prevent enteric infection.97 Thus immunoglobulin sources other than colostrum may not provide Ig that are specific for antigens present in the environment or that might be insufficient when calves are exposed to a heavy infection pressure.

The other factors that influence the ingestion of colostrum and the absorption of immunoglobulin are presented in the section on the epidemiology of colibacillosis, above, and in Chapter 3.

**Guidelines to insure transfer of colostral immunoglobulin**

Some guidelines for insuring that newborn farm animals ingest sufficient quantities of colostrum and absorb adequate amounts of colostral immunoglobulins are summarized here. Additional details are presented in Chapter 3.

**Dairy calves**

The following should be implemented:

- Immediately after birth, unless the calf is a vigorous sucker, colostrum should be removed from the cow and fed by nipple bottle or by stomach tube at the rate of at least 50 mL/kg BW in the first 2 hours.

Encouragement and assistance to suck to satiation within the first hour after birth is also highly effective in...
achieved high levels of colostral immunoglobulins in the serum of the calf. If pooled colostrum is used, calves should be fed 3-4 L of first-milking colostrum. The calf can be left with the cow for at least 2 days. This contact will improve the absorption of immunoglobulin. However, there is now a trend, at least in large dairy herds, to remove the calf immediately after birth, place it in a stall and force-feed it colostrum. This practice may also prevent spread of infectious disease from mature cattle to calves. Following the colostral feeding period, dairy calves are usually placed in individual stalls until weaning. The daily feeding of stored fermented colostrum to newborn calves for up to 3 weeks after birth provides a source of lactoglobulins in the intestinal tract and reduces the incidence of neonatal diarrhea of calves due to a wide variety of pathogens, but this practice may be impractical. Calves should be fed regularly, and preferably by the same person. One of the most important factors affecting dairy calf mortality is the concern and care provided by the calf rearer. The calf mortality rate is likely to be lower when members of the family care for the calves compared to hired help. Colostrum stored at room temperature should be handled adequately to minimize bacterial contamination. Up to 36% of colostrum samples from calf nursing bottles in dairy herds may be contaminated with Staphylococcus spp., Gram-negative rods, coliforms, and Streptococcus uberis. The relative risk of contamination with more than 100,000 bacteria/mL was greater in warm months than in cooler months, and in colostrum fed to male calves. The greater risk to male calves may reflect less attention to hygiene and management procedures compared to female calves. The housing and ventilation must be adequate to avoid stress.

**Beef calves**

The management strategies to decrease calf death losses in beef herds have been described. The role of management intervention in the prevention of neonatal deaths includes measures to improve host defenses and environmental hygiene to minimize outbreaks of neonatal disease. Specific attention is centered on preventing dystocia, improving transfer of colostral immunoglobulins, and limiting environmental contamination.

The following should be implemented:

- Management of the beef herd must emphasize prevention of dystocia, which involves limiting calf size and ensuring adequate pelvic area of the dams.
- Beef calves should be assisted at birth, if necessary, to avoid exhaustion and weakness from a prolonged parturition.
- Normally beef calves will make attempts to get up and suck within 20 minutes after birth but this may be delayed for up to 8 hours or longer. Beef calves that do not suck within 2 hours should be fed colostrum by nipple bottle or stomach tube. Whenever possible they should be encouraged and assisted to suck to satiation within 1 hour after birth. The dam can be restrained and the calf assisted to suck. If the calf is unable or unwilling to suck, the dam should be restrained and milked out by hand, and the calf fed the colostrum with a nipple bottle or stomach tube. The mean volume of colostrum and colostral immunoglobulins produced in beef cows and the absorption of colostral immunoglobulins by their calves can vary widely. Beef calves deserted by indifferent dams need special attention. Failure of transfer of passive immunity is common and estimated at 10-40% of beef calves.
- Constant surveillance of the calving grounds is necessary to avoid overcrowding, to detect diarrheic calves that should be removed, to avoid mismothering, and to insure that every calf is seen to nurse its dam. Although up to 25% of beef calves may not have sufficient serum levels of immunoglobulins, the provision of excellent management will minimize the incidence of colibacillosis. The recently developed practice of corticosteroid-induced parturition in cattle may result in a major mismothering problem if too many calves are born too quickly in a confined space. Every management effort must be used to establish the cow/calf herd as soon as possible after birth. This will require high-quality management to reduce even further the infection rate and minimize any stressors in the environment.

**Lambs**

Lambs require 180-210 mL of colostrum/kg BW during the first 18 hours after birth to provide sufficient energy for heat production. Such an intake will usually also provide enough colostral immunoglobulins. Early encouragement and assistance of the lambs to suck the ewe is important. Well-fed ewes usually have sufficient colostrum for singletons or twins. Underfed ewes may not have sufficient colostrum for one or more lambs and supplementation from stored colostrum obtained by milking other high-producing ewes is a useful practice.

**Piglets**

The following should be implemented:

- Every possible economical effort must be made to insure that each newborn piglet obtains a liberal supply of colostrum within minutes of birth. The farrowing floor must be well drained and it must be slip-proof to allow the piglets to move easily to the sow’s udder. Some herdspeople provide assistance at farrowing, drying off every piglet as it is born and placing it immediately onto a teat.
- The washing of the sow’s udder immediately before farrowing with warm water and soap will reduce the bacterial population and may provide relief in cases of congested and edematous udders.
- The piglet creep area must be dry, appropriately heated for the first week and free from drafts. During farrowing, colostrum is released in discrete ejections, possibly by discrete release of oxytocin associated with parturition. Therefore, as the piglets are born they must be as close to the udder as possible in order to take advantage of these discrete ejections.

**Increasing specific resistance of the newborn by vaccinating the pregnant dam or the newborn**

The immunization of neonate farm animals against colibacillosis by vaccination of the pregnant dam or by vaccination of the fetus or the neonate has received considerable research attention in recent years and the results appear promising. Such vaccines are practical and effective because:

- Most fatal enterotoxigenic E. coli infections in farm animals occur in the early neonatal period when antibody titers in colostrum and milk are highest.
- More than 90% of the enterotoxigenic E. coli in farm animals belong to a small family of fimbrial antigens.
- Fimbriae consist of good protein antigens on the bacterial surface where they are readily accessible to antibody.
- Fimbriae are required for a critical step (adhesion–colonization) early in the pathogenesis of the disease.
- Novel or previously low-prevalence fimbrial antigens have not emerged to render the vaccines ineffective.
The pregnant dam is vaccinated 2-4 weeks before parturition to induce specific antibodies to particular strains of enteropathogenic *E. coli*, and the antibodies are then passed on to the newborn through the colostrum. The mechanism of protection is the production of antibodies against the pilus antigens, which are responsible for colonization of the *E. coli* in the intestine.102

**Vaccination is an aid to good management and not a replacement for inadequate management.** Vaccines to prevent enterotoxigenic *E. coli* diarrhea in calves and piglets are based on the prevailing fimbrial antigens for colonization by enterotoxigenic *E. coli* in calves (F5) and newborn pigs (F4, F5, and F6). Reliable data on the efficacy of the commercial vaccines based on randomized clinical field trials are not available but most animal health professionals perceive that the vaccines are effective and that disease occurs primarily in unvaccinated herds. There are unpublished anecdotal reports that use of the vaccine in cattle has shifted the peak occurrence of diarrhea in calves from the first week to the third and fourth week after birth. The extensive use of fimbriae-based vaccines can select against the prevailing fimbrial antigen types as reflected in the vaccines, and emergence of new or previously low-prevalence fimbrial antigens may occur. Fimbriae antigenically distinct from F1, F4, F6, F41 occur among enterotoxigenic *E. coli*. However, these antigen types are less prevalent than those currently used in commercial vaccines. There is no evidence that enterotoxigenic *E. coli* with novel colonization mechanisms or new fimbrial antigens have emerged under the selection pressure of vaccination. Nor is there evidence that previously 'low-prevalence' fimbrial antigen types enterotoxigenic *E. coli*, not represented in the vaccines, have emerged as 'common pathogens' filling an ecological niche left by the fimbrial antigen types targeted by the vaccines.

Calves

Vaccination of pregnant cattle with either purified *E. coli* K99* pili or a whole-cell preparation containing sufficient K99* antigen can significantly reduce the incidence of enterotoxigenic colibacillosis in calves. Good protection is also possible when the dams are vaccinated with a four-strain *E. coli* whole-cell bacterin containing sufficient K99* pilus antigen and the polysaccharide capsular K antigen. Colostral antibodies specific for K99* pilus antigen and the polysaccharide capsular K antigen on the surface of the challenge exposure strain of enterotoxigenic *E. coli* are protective. There is a highly significant correlation between the lacteal immunity to the K99* antigen and the prevention of severe diarrhea or death in calves challenged with enterotoxigenic *E. coli*. The colostral levels of K99* antibody are highest during the first 2 days after parturition, which is the most susceptible period for enterotoxigenic colibacillosis to occur in the newborn calf. The continuous presence of the K99* antibody in the lumen of the intestine prevents adherence of the bacteria to the intestinal epithelium. The K99* antibody is also absorbed during the period of immunoglobulin absorption and may be excreted into the intestine during diarrhea. This may be one of the reasons that mortality is inversely proportional to serum immunoglobulin levels. The pregnant dams are vaccinated twice in the first year, 6 and 2 weeks prior to parturition. Each year thereafter they are given a single booster vaccination. An oil emulsion *E. coli* K99* bacterin given once or twice to pregnant beef cows 6 weeks before calving elicited high levels of serum antibody that provided protection against experimental infection of newborn calves for up to 87 weeks after vaccination.

Vaccines containing both the K99* antigen of enterotoxigenic *E. coli* and rotavirus, and in some cases coronavirus, have been evaluated with variable results. The colostral antibodies to the K99* antigen are higher in vaccinated than unvaccinated dams but the colostral antibodies to rotavirus and 'coronavirus may not be significantly different between vaccinated and unvaccinated dams. In these field trials vaccination had no effect on the prevalence of diarrhea, calf mortality or the presence of the three enteropathogens. In other field trials the combined vaccine did provide some protection against outbreaks of calf diarrhea. The use of an inactivated oil-adjuvanted rotavirus *E. coli* vaccine given to beef cows 6 weeks before calving elicited high levels of serum antibody that provided protection against experimental infection of newborn calves for up to 87 weeks after vaccination. A definitive diagnosis of enteropathogenic K99* *E. coli* in the previous year.

**A population density in the calving grounds that is conducive to the disease**

Calves

- Calves vaccinated for K99 antigens can reduce the incidence of enterotoxigenic colibacillosis.
- A large portion of the newborn calves are protected if the dams are vaccinated.

Piglets

- Piglets are protected when the dams are vaccinated or the piglets are treated after birth.
- The use of a combined vaccine may be beneficial in controlling morbidity and mortality.

The decision to vaccinate in any particular year will depend on the recognition of risk factors. Such risk factors include:

- A definitive diagnosis of enterotoxigenic K99* *E. coli* in the previous year.
- A population density in the calving grounds that is conducive to the disease.
Calving during the year when the environmental conditions are wet and uncomfortable for the calves.

A large percentage of primiparous dams that do not have protective levels of K99* antibody in their colostrum.

Piglets
Piglets born from gilts are more susceptible than those from mature sows, which suggests that immunity improves with parity. On a practical basis this suggests that gilts should be mixed with older sows that have been resident on the premises for some time. The length of time required for such natural immunization to occur is uncertain, but 1 month during late gestation seems logical.

Naturally occurring enteric colibacillosis in newborn piglets can be effectively controlled by vaccination of the pregnant dam. Field trials in large-scale farm conditions indicate that the vaccines are efficacious. Partial budget analysis of vaccinating pregnant sows with E. coli vaccines revealed an economic return on investment of 124% because of the decrease in morbidity and mortality due to diarrhea in piglets 1–2 weeks of age.

Three antigen types of pili, designated K88*, K99*, and 987P, are now implicated in colonization of the small intestine of newborn piglets by enterotoxigenic E. coli. The vaccination of pregnant sows with oral or parenteral vaccines containing these antigens will provide protection against enterotoxigenic colibacillosis associated with E. coli bearing pili homologous to those in the vaccines. The parenteral vaccines are cell-free preparations of pili, and the oral vaccines contain live enteropathogenic E. coli. The oral vaccine is given 2 weeks before farrowing and is administered in the feed daily for 3 days as 200 mL per day of a broth culture containing 10^8 E. coli. A simple and effective method of immunization of pregnant sows is to feed live cultures of enterotoxigenic E. coli isolated from piglets affected with neonatal colibacillosis on the same farm. The oral vaccine can be given in the feed, beginning about 8 weeks after breeding and continued to parturition. The oral vaccine results in the stimulation of IgA antibody in the intestinal tract, which is then transferred to the mammary gland and into the colostrum. A combination of oral and parenteral vaccination is superior to either route alone. The parenteral vaccine is given about 2 weeks after breeding and repeated 2–4 weeks before parturition. The parenteral vaccination results in the production of high levels of IgM antibody for protection against both experimental and naturally occurring enterotoxigenic colibacillosis. This vaccination also reduces the number of E. coli excreted in the feces of vaccinated sows, which are major sources of the organism. Immunization of pregnant sows with an E. coli bacterin enriched with the K88* antigen results in the secretion of milk capable of preventing adhesion of K88* E. coli to the gut for at least 5 weeks after birth, at which time the piglet becomes naturally resistant to adhesion by the organism.

The possibility of selecting and breeding from pigs that may be resistant genetically to the disease is being explored. The highest incidence of diarrhea occurs in progeny of resistant dams and sired by susceptible sires. The homozygous dominants (SS) and the heterozygotes (Ss) possess the receptor and are susceptible whereas in the homozygous recessives (ss) it is absent and the pigs are resistant. Sows that are genetically resistant may not be able to mount an immune response to the K88* antigen because of the inability of the organism to colonize the intestinal tract.

Competitive exclusion culture
An alternative method of control is the use of competitive exclusion cultures. The theory of competitive exclusion technology is to colonize the neonatal gastrointestinal tract with beneficial commensal bacteria considered to be the normal flora of the healthy animals of a particular species. The mechanism of action is not known but hypotheses include: exclusion of enteropathogens by competitive attachment sites and/or for nutrients; stimulation of the local immune mechanisms, which preclude colonization/invasion by enteric pathogens; and the production of various antimicrobial substances that either have direct action on pathogenic bacteria or produce conditions within the intestine that are unfavorable for the growth and colonization by pathogens. Experimentally, the oral administration of a porcine competitive exclusion culture to piglets within 12 hours after birth resulted in significant reductions in mortality, incidence of fecal shedding, and intestinal colonization by E. coli when compared to control values. Mortality decreased from 23% in the control group to 2.7% in the treated group.

Lambs and kids
Vaccination of pregnant ewes with K99* antigen will confer colostral immunity to lambs challenged with homologous enteropathogenic E. coli. The pregnant ewes are vaccinated twice in the first year, at 8–10 weeks and 2–4 weeks before lambing, and in the second year one vaccination 2–4 weeks before lambing is adequate.

Immunization of pregnant goats has been used to stimulate the development of lactic immunity against naturally occurring colibacillosis in kids. Vaccination of pregnant does 1 month before parturition with a subunit vaccine containing K88, K9, and 987P fimbrial antigens of E. coli, and C. perfringens types B, C, and D toxins in an aluminum hydroxide adjuvant, along with improved management conditions, was highly successful in reducing neonatal morbidity and mortality due to diarrhea. Compared to two control groups, one in which no improvement in management was made and the second in which improvements were made without vaccination, in the vaccinated group with improved management conditions, neonatal morbidity and mortality were both reduced by a factor of 3 in Group 1 and by factors of 9.5 and 12.5 in Group 3. Also, the duration of diarrhea was 3.7 and 12 times shorter in the kids of Groups 2 and 3, respectively.

Naturally occurring cases of attaching and effacing lesions of the intestines in calves with diarrhea and dysentery and infected with E. coli O126:H11, the predominant verotoxin-producing E. coli in humans, have been described in the UK. Verotoxin-producing E. coli and aerotolerant non-verotoxin-producing E. coli have been isolated from diarrheic dairy calves 1–30 days of age.3

**EPIEDEMOLOGY**

The literature of the epidemiological surveys on the prevalence of contamination of healthy cattle with *Escherichia coli* O157:H7 has been reviewed,4 as has the literature on the epidemiology and ecology of *E. coli* O157:H7 in bovine production environments.5

**Occurrence and prevalence of infection**

Cattle

Cattle are nonclinical natural reservoirs of *E. coli* O157:H7. Estimates of the prevalence of verotoxin-producing *E. coli* fecal carriage among populations of cattle vary considerably.

The herd prevalence of infection with *E. coli* O157:H7 in North American and European cattle herds ranges from 3–8% and 0.5–1.0% of animals, with a higher prevalence up to 5% in weaned calves and heifers.5 Some surveys reported the organism in dairy and beef cattle at 0.28% and 0.71%, respectively.6 Other studies found much higher levels of prevalence, such as 15.7% of cattle over a 1-year period. Monthly prevalences ranged from 4.8–36.8% and were highest in the spring and late summer.

The prevalence of *E. coli* O157:H7 is influenced by numerous variables, including the season, the scope, frequency and timing of sampling, and the conditions of sampling and storage. The organism can be found widely distributed in samples from several types of cattle including beef calves, stocker cattle, feedlot cattle, adult beef cows, dairy calves, water sources and wildlife.7 The prevalence is commonly higher in feeder-age cattle.

The prevalence of *E. coli* O157:H7 infection in range beef calves at weaning prior to arrival at the feedlot varies from 17–20.0% with an average of 7.4%.8 All herds had high prevalence of anti-O157 antibodies, ranging from 63–100% of individuals within herds. Most calves (83%) and all herds (100%) have been exposed to *E. coli* O157:H7. In a naturally infected cow/calf herd followed over a period of 2 years, postpartum shedding of *E. coli* O157:H7 and cow/calf or calf-calf transmission under confined conditions in the postpartum period appeared to be potentially important factors in initial infection of beef calves.9 Parturition, calving pens and weaning appear to be important factors in maintaining *E. coli* O157:H7 infections in some herds.

Different serotypes of verotoxin-producing *E. coli* known to cause human illness have been found in the feces of culled beef cows at the time of shipping to slaughter.10 The diversity, frequency, and persistence of *E. coli* O157:H7 strains in cattle, wildlife and water sources within range cattle production environments indicates that the molecular epidemiology of the organism is very complex.11

The prevalence of *E. coli* O157:H7 in dairy calves is similar worldwide and ranges from 1–5% in heifers and less than 1% in adult cattle. The herd-level prevalence varies from 0–100%. The herd-prevalence of *E. coli* O157:H7 in dairy cattle in the subtropical southeastern USA in the summer months was 38.5%, and the cow-level prevalence was 6.5%.12 Among positive herds, prevalence ranged from 3–35%. The prevalence was higher during the spring and summer months compared to the winter season. Site-specific prevalences of *E. coli* O157:H7 from the oral cavity, skin, and fecal samples were 0%, 0.7%, and 25.2% respectively. Interestingly, in these same areas, reported cases of *E. coli* O157:H7 infections in humans are relatively uncommon and do not support the hypothesis that *E. coli* O157:H7 infections in humans are rare in southern states because of the low prevalence in cattle.

Viable *E. coli* O157:H7 can be isolated from the oral cavity, multiple hide surfaces and feces of a high percentage of feedlot beef cattle, and bacterial culture of feces alone generally underestimates the prevalence of *E. coli* O157:H7 in feedlot cattle.13 A survey of 60 Danish dairy cattle farms found a herd-prevalence of *E. coli* O157:H7 of 17% and an individual animal prevalence of 3.6%.14 The high-risk age group for *E. coli* O157:H7 was calves between 2 and 6 months of age (8.6% positive), in contrast to calves under 2 months of age (0.7%) and cows (2.4%).14

*E. coli* O157:H7 is widespread in cattle in England and Wales. During a survey between June and December, the herd-prevalence on positive farms ranged from 1.1–51.4%, and the overall individual animal prevalence was 4.2%, and 10.3% among animals in positive herds.15 The prevalence of excretion was least in calves under 2 months of age, peaked in calves between 2 and 6 months of age and declined thereafter. Multiple phage types of *E. coli* O157:H7 were isolated from almost a third of the herds, and the phage types were similar to those responsible for human infections in England and Wales during the same period. Similar prevalences have been found in dairy cattle in Brazil.16

Attaching and effacing *E. coli* (AEC) of various strains have been associated with naturally occurring and experimental dysentery in calves, and outbreaks of hemorrhagic enteritis with attaching and effacing lesions of the colon associated with *E. coli* O126 infection have occurred in heifers 8–12 months of age.17 *E. coli* O126 is recognized as an enterohemorrhagic pathogen in humans.

Prevalence of infection in cattle, sheep, and pigs at slaughter

Based on fecal sampling, the prevalence rate of infection of cattle with *E. coli* O157:H7 varies considerably. Based on fecal samples from the rectums of cattle at slaughter in the UK, the animal-level prevalence was 7.5% and the group prevalence was 40.4%.18 Of the infected animals, 9% were high shedders whose feces contained *E. coli* O157:H7 at concentrations of more than 10⁴ colony-forming units (cfu)/g. This 9% also represented more than 96% of the total *E. coli* O157:H7 produced by all animals tested. This indicates that the presence of high-shedding animals at the abattoir increases the potential risk of beef contamination during the slaughtering process and stresses the need for correct hazard analysis and critical control points procedures.

There is a correlation between the prevalence of *E. coli* O157:H7 in the feces, hides and carcasses of beef cattle during slaughter.19 Overall, the prevalence of *E. coli* O157:H7 in feces and on hides was 28% and 11%, respectively. Carcass samples were taken at three points during processing: pre-evisceration, post-evisceration before antimicrobial intervention, and postprocessing after carcasses entered the cooler. The prevalence of *E. coli* O157:H7 in the three post processing samples was 43%, 18%, and 2%, respectively. Antimicrobial intervention included steam pasteurization, hot water washes, organic acid washes, or combinations of these treatments. The reduction in carcass prevalence from pre-evisceration to post-processing suggests that sanitary procedures can be effective within processing plants. Fecal and hide prevalence were significantly correlated with carcass contamination, indicating a role for control of *E. coli* O157:H7 in live cattle.

The prevalence of fecal carriage of *E. coli* O157:H7 in cattle and sheep sampled throughout the year at the abattoir before slaughter was 4.7% for cattle and 1.7% for sheep.20 The most frequently recovered *E. coli* O157:H7 isolates were phage types 2, 8, and 21/28 in cattle and
4 and 32 in sheep, the five most frequently isolated phage types associated with illness in people in Great Britain during the same survey period. In a commercial beef abattoir in Ireland, carcass contamination with E. coli O157:H7 can occur during removal of the hide and tying the bung, and this contamination can remain on the carcass during subsequent processing.

The prevalence of attaching and effacing E. coli isolated from cattle, sheep, and pigs at slaughter in England and Wales was 8.1%, with a frequency of 18% in sheep, 6% in cattle, and less than 1% in pigs. Several different eae-positive serogroups were isolated; some possessed stx1 but none had stx2.

An overall prevalence of E. coli O157:H7 fecal shedding by New York cul dairy cattle of 1.3% was found in specimens just before processing the packing plant.

In a survey of downer cattle submitted to two slaughter facilities in Wisconsin, the prevalence of E. coli O157:H7 in the feces and/or tissues of downer dairy cattle was 4.9% compared to 1.5% in healthy cattle.

PCR has been used to detect virulence genes and molecular epidemiology of E. coli O157:H7 isolates from abattoirs. Samples included swabs of tools, knives and saws, fecal samples, carcass samples and ears removed after slaughter. From 1432 samples, 143 E. coli O157:H7 strains were isolated. These results indicate the increase in contamination frequencies during transportation to the abattoir and the lairage period before slaughter, as a result of cross-infection caused by mixing of animals from different sources.

Surveys at the abattoir could be useful in detecting infected cattle herds and allow focusing on potentially infected herds, in concert with on-farm surveys.

Sheep and goats
Sheep and goats can be naturally infected with E. coli O157:H7 and sheep have been used as a model of ruminant infection. Sheep may harbor E. coli O157:H7 and non-O157:H7 verotoxin-producing E. coli at rates similar to or higher than in cattle. Prevalence rates of 67% and 45% have been reported in Germany and Australia, respectively. Worldwide, sheep have been shown to shed several non-O157 verotoxin-producing E. coli in their feces.

Several of these verotoxin-producing E. coli serotypes have been associated with sporadic cases or major outbreaks of human illnesses. Thus lamb, mutton, and their products share a food safety risk factor similar to that of beef. Non-O157:H7 verotoxin-producing E. coli have been found in sheep grazing irrigated pasture or arid rangeland forage in Nevada. In Norway, sheep have carried Shiga-toxin-producing E. coli serogroups O5, O91, and O128, and their virulence factors have been characterized. In Brazil, Shiga-toxin-producing E. coli occurred in the feces of 51% of healthy sheep grazing on pasture. The serotypes could cause severe disease in humans.

Wildlife
Based on fecal samples of deer submitted by hunters, E. coli O157:H7 have been found in the feces of free-ranging white-tailed deer in Nebraska at a rate of 0.25%. The prevalence of infection of E. coli O157:H7 in white-tailed deer sharing rangeland with cattle was 2.4%. The low overall prevalence of E. coli O157:H7 and the identification of only one site with positive deer suggest that wild deer are not a major reservoir of E. coli O157:H7 in the southeastern USA.

Pigs
E. coli O157:H7 has been found in fecal samples of finished pigs at the time of slaughter but the prevalence was very low at 0.08%. In experimentally infected pigs, E. coli O157:H7 can persist for more than 2 months. Pigs may have the potential to be reservoirs hosts for E. coli O157:H7 but the magnitude of the risk needs to be determined.

Risk factors
Animal risk factors
Healthy normal cattle are a major reservoir for enterohemorrhagic E. coli O157:H7 strains, which cause disease in humans. Cattle that are infected with E. coli O157:H7 remain free of disease and are tolerant of E. coli O157:H7 for their entire lives. Neonatal calves under 36 hours of age are susceptible to experimental inoculation with E. coli O157:H7 and develop attachment and effacing lesions in both the large and small intestines. Neither experimentally infected calves nor older cattle with E. coli O157:H7 develop extraintestinal vascular lesions. The lack of vascular receptors for Stx in cattle renders them resistant to the Stx. Neither viable E. coli O157:H7 nor Stx-containing extracts cause fluid accumulation in ligated ileal loops of newborn calves, whereas doses of Stx did cause fluid accumulation experimentally in rabbits.

Environmental and management risk factors
The factors associated between management, climate, and the prevalence of E. coli O157:H7 in feedlot-water tanks and in feedlot-cattle feed have been examined in selected feedlots in the USA. E. coli O157:H7 was isolated from 13% of the water tanks and at least one water tank was positive on 60% of the feedlots. The factors associated with E. coli O157:H7 in water were a greater percentage of cattle shedding E. coli O157:H7 in the feces within the pen, higher concentrations of total E. coli in the water, lack of clarity of the water, the use of fly traps, the reported frequency of rodent sightings in the pen or alley area, and the weather at the time of sampling. E. coli O157:H7 was isolated from 14.9% of the feed samples obtained from the feedbunks. Factors positively associated with E. coli O157:H7 in the feed were higher heat index at the time of sampling, the presence of cottonseed meal in the ration, and the feedlot location.

The association between management, climate and E. coli O157:H7 in the feces of feedlot cattle in the midwestern USA has been examined. The prevalence of E. coli O157:H7 was 10.2% at the sample level, 52.0% at the pen-level and 95.9% at the feedlot level. The factors associated with the presence of E. coli O157:H7 in cattle feces were the frequency of observing cats in the pens or alleys, the presence of E. coli O157:H7 in the water tanks (positive association), the historical use of injectable mass medication (positive association), the use of antibiotics in the ration or water (negative association), the wetness of the pen, number of cattle in the pen (negative association), wind velocity (positive association), and height of the feed bunk (positive association).

Housing and management practices
Environmental dissemination of an inoculated strain of E. coli O157:H7 given to dairy calves spreads more quickly when calves are housed in groups compared to calves housed in individual pens from 7–110 days of age. This indicates that control may depend on reduction of horizontal transmission within cattle groups, thus decreasing prevalence. The use of segregated penning systems rather than group housing of weaning calves may reduce the prevalence of these potential pathogens within the calf unit. If this results in a reduction in the general herd or farm Shiga-toxin-producing E. coli prevalence, then such changes in calee-rearing practice maybe to prevent herd Shiga-toxin-producing E. coli risk on dairy farms.

The housing of beef suckler cows in Scotland during the winter months was associated with increased level of shedding of E. coli O157:H7.

Pathogen risk factors
Virulence attributes and mechanisms
The primary feature of Shiga-toxin-producing E. coli isolates is their ability to produce potent cytotoxins encoded by
Acid resistance
E. coli O157:H7 is extremely acid-resistant, which contributes to the low infectious dose for humans, which has been estimated to be fewer than 700 cells and possibly even as low as 10.26 Certain strains of E. coli O157:H7 have been considered to be more acid-tolerant than some commensal E. coli. In addition, E. coli O157:H7 strains may become acid-habituated by exposure to weak acids in the rumen. Consequently, E. coli O157:H7 may survive passage through the acid barrier in the stomach, colonizing and replicating in the ruminant colon. The numbers of E. coli O157:H7 are much higher in the colon than the rumen.49

The acid-resistance characteristics of E. coli O157:H7 led to the hypothesis that feeding grain to cattle created an ideal environment in the gastrointestinal tract to promote the growth and persistence of the organism. The research data on the effects of grain versus forage feeding to cattle and its effects on fecal E. coli O157:H7 are limited and conflicting. Some early research indicated that grain feeding increased the dissemination of acid-resistant E. coli by cattle, and that feeding hay for a brief period immediately before slaughter would decrease the shedding of E. coli O157:H7. The numbers, persistence and acid resistance of generic coliforms and E. coli O157:H7 from various gastrointestinal tract sites of cattle fed grain or hay were compared. Grain-feeding or hay-feeding did not affect survival of E. coli O157:H7 in the rumen, nor its passage through the abomasum (pH 2.0) to the duodenum.51

Generic coliforms from the rumen and rectum of hay-fed animals were more sensitive to an acid shock than coliforms from gut locations in grain-fed animals. Thus E. coli O157:H7 in bovine ingesta are acid-resistant regardless of animal diet.51 Abruptly switching cattle from a high-grain diet to a high-quality hay-based diet has been shown to reduce generic E. coli and E. coli O157:H7 populations but the magnitude of the reduction has varied among studies.42,43

Other work has shown that, in the context of acid tolerance, E. coli O157:H7 does not appear to be greatly different from commensal E. coli.44 However, E. coli O157:H7 may have the ability to generate a higher ‘tail’ population and this, together with the low infective dose and changes in our lifestyle, has allowed the organism to become a major pathogen. Recent studies on the effect of forage or grain diets have shown that cattle fed forage diets had ruminal persistence of fecal E. coli O157:H7 at quantifiable concentrations for twice as long as cattle fed grain diets.45 Diets high in grain generate lower volatile fatty acid concentrations and lower ruminal pH in cattle, whereas lower volatile fatty acid concentrations and higher pH in forage-fed cattle may be more conducive to the growth and survival of the organism. Monensin supplementation decreased the duration of shedding with forage diet, and the cecum and colon were culture-positive for E. coli O157:H7 more often than the rumen of cattle.46

Antimicrobial resistance
The prevalence of antimicrobial resistance among isolates of E. coli O157:H7 recovered from clinical cases in humans, pigs, cattle, and food over a 15-year period (1985–2000) in the USA has been described.46 There was a high prevalence of resistance to tetracycline, sulfamethoxazole, cephalothin, and ampicillin. The highest prevalence occurred among isolates from pigs, where more than 50% of all isolates were resistant to sulfamethoxazole, cephalothin, or tetracycline and more than 20% were resistant to ampicillin or gentamicin.
Water supplies for livestock

Drinking water offered to cattle is often of poor microbiological quality and the daily exposure of animals to E. coli O157:H7 from this source can be substantial. The degree of E. coli exposure is positively associated with proximity of water troughs to the feed bunk, protection of the trough from sunlight, and warmer weather. Cattle water troughs can serve as environmental reservoirs for E. coli O157:H7 and as a long-term source infection for cattle.

The experimental inoculation of E. coli O157:H7 with 1 L of water into dairy calves in a confined environment resulted in shedding of the organism by the calves within 24 hours after administration. The duration of shedding varied from 18 to more than 43 days and the number of doses necessary to initiate shedding varied among calves. E. coli O157:H7 is present in as many as 10% of water troughs. E. coli O157:H7 was present in the water or water-tank sediment in 13.1% of water tanks in a feedlot in the USA and 60% of feedlots had at least one positive tank.

Cattle were more likely to be shedding E. coli O157:H7 in pens with positive water tanks, and water was more likely to be positive when E. coli O157:H7 was detected in the sediment.

Chlorination of input water in feedlots was unable to reduce the prevalence of E. coli O157:H7-contaminated water troughs.

Water trough sediments with feces from cattle excreting E. coli O157:H7 may serve as a long-term reservoir of the organism on farms and a source of infection for cattle. The accumulation of large amounts of organic matter would be expected to rapidly inactivate the biocidal activity of chlorine and provide an ideal niche for the survival of the organism.

E. coli O157:H7 can survive in farm water under field and shed conditions at temperatures less than 15°C for up to 24 days. The addition of feces to water outdoors resulted in survival for 24 days.

e. coli O157:H7 has been isolated from surface waters collected from a Canadian watershed. Systematic sampling of surface water within the Oldman River basin in southern Alberta reveals that it often contaminated with E. coli O157:H7 and Salmonella spp. The prevalence of E. coli O157:H7 and Salmonella spp. in water samples was 0.9% and 6.2%, respectively. The region surveyed is noted for high cattle density as well as for one of the highest incidences of gastroenteritis in Canada, resulting from infection by Salmonella spp. and E. coli O157:H7. While the data indicated a relationship between high livestock density and high pathogen levels in southern Alberta, analysis of the point source data indicates that the predicted manure output from cattle, pig, and poultry feeding operations was not directly associated with the prevalence of either Salmonella spp. or E. coli O157:H7. Variations in time, amount and frequency of manure applications on to agricultural lands may have influenced levels of surface-water contamination with these bacterial pathogens.

Feed supplies

The prevalence of E. coli O157:H7 in cattle feeds in feedlots was 14.9%, higher than previously reported, which may be due to more sensitive detection methods. Feed may be a vehicle for dissemination and colonization; however, the source of the E. coli O157:H7 contamination in cattle feed is uncertain. Possible sources include saliva and fecal contamination by cattle or other species, or by wildlife, including birds, rodents, and insects. Another possible source is contaminated feed components mixed into the feed. PFGE profiles of E. coli O157:H7 isolated from a component feed sample closely resembled that isolated later from the same farm, suggesting that cattle feed may be an important vector for the transmission of E. coli O157:H7.

Manure

Survival of E. coli O157:H7 in manure and manure slurry has been observed under various experimental and environmental conditions. The use of manure as fertilizer could explain foodborne outbreaks of E. coli O157:H7 associated with unpasteurized apple cider, potatoes, and other vegetables. Because E. coli O157:H7 can survive for extended periods of time, proper manure management is of major importance in preventing the spread of this organism to the environment. Composting is an effective method for eliminating pathogens such as E. coli O157:H7 from manure.

Soil

E. coli O157:H7 inoculated into loam and clay soils can survive for 25 weeks and in sandy soils for up to 24 weeks. Detection of E. coli O157:H7 in soil suggests the possibility of an inoculum in the soil. The development of a method for soil samples may prove useful for environmental monitoring.
sandy soil for 8 weeks. The organism was detectable for up to 7 days after inoculation into the uppermost 2.5 cm of the soil, and for up to 7 days on grass plots inoculated with a fecal slurry from dairy cattle at an application rate of E. coli O157:H7 of 660 cfu/m².

**Animal-holding facilities**
The organism can be cultured from rope devices in a feedlot pen that cattle rub or chew and there is a correlation with the prevalence of cattle shedding the organism in the feces from within the same pen.63 This pen-test strategy may be useful to identify pens of cattle posing a higher risk to food safety.

**Immune mechanisms**
The Esp and Tir proteins secreted by E. coli O157:H7 play critical roles in the development of the attaching and effacing lesions and are recognized serologically in human patients with the hemolytic crisis syndrome. Antibodies to intimin, Esp and Tir proteins have been detected in HUS patients following infections with E. coli O157:H7.63

In contrast, little is known about the immune responses of cattle to infection with E. coli O157:H7.64 E. coli O157:H7 and other enterohemorrhagic E. coli are shed sporadically by cattle, and it appears that natural exposure to E. coli O157:H7 does not confer protection on the host. Calves 13–30 days of age developed anti-O157 IgG responses following experimental oral inoculation with E. coli O157:H7.65 Mature cows did not develop a significant increase in their serum anti-O157 IgG levels following oral inoculation. These observations suggest that local immunity to E. coli O157:H7 may not develop to any degree in the intestine and that immunization to reduce fecal shedding of E. coli O157:H7 may not be effective.

Vaccination of cattle with antigenic bacterial proteins involved in colonization can significantly reduce fecal shedding and prevalence of E. coli O157:H7 in cattle. Vaccination of cattle with E. coli O157:H7 type III secreted proteins can reduce the numbers of E. coli O157:H7 shed in the feces, and the duration of shedding in experimentally challenged cattle, and in feedlot cattle under field conditions.66 Vaccination of pregnant gilts with intimin from E. coli O157:H7 induced high intimin-specific immune responses in the serum and colostrum, and suckling neonatal piglets had reduced bacterial colonization and intestinal lesions following experimental challenge.67 These results suggest that vaccination may be a useful preharvest strategy for reducing the prevalence of E. coli O157:H7 infection in cattle.

**Zoonotic implications**

However secure and well-regulated civilized life may become, bacteria, protozoa, viruses, and infected fleas, lice, ticks, mosquitoes, and bedbugs will always lurk in the shadows ready to pounce when neglect, poverty, famine, or war lets down the defenses. And even in normal times they prey on the weak, the very young and the very old, living along with us in mysterious obscurity awaiting their opportunities.

Zinsser, 1934

The above wisdom relates to E. coli O157:H7.

Enterohemorrhagic strains of E. coli, especially serotype E. coli O157:H7, have been linked in humans with hemorrhagic colitis, hemolytic–uremic syndrome and thrombocytopenic purpura from eating contaminated foods, such as beef and dairy products, vegetables, and apple cider, from contaminated drinking water or from contact with infected animals or contaminated environments. As few as 10 E. coli O157:H7 bacteria can cause illness in humans.

In 1999, the Centers for Disease Control and Prevention estimated that 73,480 people per year in the USA were infected with E. coli O157:H7 and that 61 of these cases were fatal.68 Most cases of E. coli O157:H7 illness are attributable to food-borne infection; however, acquisition of disease by direct contact with animals and manure at petting zoos and dairy farms are of increasing concern. Among E. coli O157:H7 foodborne outbreaks in 1999, one-third were due to beef; historically, undercooked ground beef is the most common vehicle. Consumption of pink hamburgers at home or in restaurants is a risk factor for E. coli O157:H7 infection. Microbiological testing of ground beef patties from a large outbreak that occurred in the Pacific northwest between November 1992 and February 1993 suggested that the infectious dose for E. coli O157:H7 is fewer than 700 organisms. This represents a strong argument for enforcing zero tolerance for this organism in processed food and for markedly decreasing contamination of raw ground beef. A major source of the bacteria in ground beef is bovine feces, which contaminates carcasses before evisceration; the organism is thought to be spread from contaminated hides to the surfaces of carcasses at slaughter. In addition to feces and hides, E. coli O157:H7 has been isolated from the oral cavities of cattle.

In May 2000, E. coli O157:H7 and Campylobacter jejuni contaminated the drinking water supply in Walkerton, Ontario, Canada.69,70 As a result, seven people died and over 2000 became ill. The pathogen causing the outbreak were attributed to contamination of the town’s water well arising from cattle manure from a nearby cattle farm following a period of heavy spring rainfall. Failure to adequately chlorinate the water supply resulted in the contaminated water being consumed by the people in the town.

Argentina has one of the highest recorded incidence of hemolytic–uremic crisis in the world at 300–400 cases per year.38 It also has the highest per capita consumption of beef of any country in the world.

Visits to farms for recreational or educational purposes have become an important part of the tourism and leisure industries in some countries.71 The emergence of E. coli O157:H7 with its very low infectious dose and associated risks of serious human illness, has greatly increased the potential for zoonotic disease acquired from livestock, including those on open farms. The livestock of these farms may include sheep, goats, mature cattle and calves, pigs, donkeys, ponies, rabbits, guinea pigs, chipmunks, laying hens, bantams, ducks, geese, and a variety of waterfowl. Outbreaks of E. coli O157:H7 infection have occurred in people visiting these farms and the E. coli O157:H7 has been isolated primarily from the calves and goats.

In a large outbreak of E. coli O157:H7 infections among visitors to a dairy farm, predominantly children, high rates of carriage of E. coli O157:H7 among calves and young cattle most probably resulted in contamination of both the hides of the animals and the environment.58,69 Contact with calves and their environment was associated with an increased risk of infection, whereas hand-washing was protective. Thirteen percent of the cattle were colonized with E. coli O157:H7, which had the same distinct pattern on PFGE found in isolates from the patients. The organism was also recovered from surfaces that were accessible to the public.

Phenotyping and genotyping of E. coli O157:H7 has been used to verify transmission of the organism from dairy cattle to humans with E. coli O157:H7 infections.72 The isolates from cattle and humans were indistinguishable, which indicates that the infection originated from the farms. However, it may not be possible to determine whether the source was unpasteurized milk or direct or indirect contact with cattle.

Transmission of E. coli O157:H7 occurs by three major routes: food items such as undercooked meat or unpasteurized milk, person-to-person spread, and direct or indirect contact with animals. Infections
have been associated with visits to cattle farms and farms open to the public, with consumption of farm products, and with camping on a cattle-grazing site. Infections have also been described in farm family members and other farm dwellers.

Undercooked beef products, unpasteurized milk and dairy products, and contaminated water are all potential vehicles for human infection with *E. coli* O157:H7.

**Economic importance**
The economic consequences of beef contaminated with *E. coli* O157:H7 are enormous. Since 1994 in the USA, millions of kilograms of ground beef have been recalled from retail outlets because of contamination with *E. coli* O157:H7. Such beef products must be destroyed and not used for animal or human food. Human illness associated with the most common food-borne pathogens alone cost the US economy more than $7 billion each year. Some of these human outbreaks have been linked to the consumption of meat-based products or to contact with animals and their wastes.

**PATHOGENESIS**

Enterohemorrhagic *E. coli* are characterized by the presence of Shiga toxin (Stx) genes, locus for enterocyte effacement (LEE) and a high-molecular-weight plasmid that encodes for a hemolysin. These three virulence factors are present in most *E. coli* associated with bloody diarrhea and hemolytic-uremic syndrome in humans.

The LEE is a large cluster of genes that are collectively responsible for the intimate attachment of the bacterium to the apical membrane of the enterocyte and subsequent destruction or effacement of the microvilli. The intimate attachment of the bacterial cell to the epithelium is attributed to the adhesin intimin and Tir, a bacterial protein, which is inserted into the host membrane and serves as the response for intimin. Both factors are part of the LEE in enteropathogenic *E. coli* and enterohemorrhagic *E. coli*. Intimin appears to be an essential component in initiating attachment, colonization and the subsequent pathological changes that follow infection with enteropathogenic *E. coli* and enterohemorrhagic *E. coli*.

*E. coli* O157:H7 also possesses a high-molecular-weight plasmid that contains several putative virulence genes, including a pore-forming hemolysin. Virulence plasmids are common features of pathogenic *E. coli*, encoding toxins, adhesins and other factors necessary for colonization, survival, and ability to cause disease in its animal host.

In ruminants, *E. coli* O157:H7 persists and proliferates in the lower gastrointestinal tract and does not remain for long periods in the ruminant stomachs or duodenum. *E. coli* O157:H7 exhibits a novel tropism for the terminal rectum in cattle. In calves experimentally infected with *E. coli* O157:H7, in almost all persistently colonized animals, the majority of tissue-associated bacteria identified are in a region within 3-5 cm proximal to the rectoanal junction. This region contains a high density of lymphoid follicles, and microcolonies of the bacterium are readily detectable on the epithelium of this region by immunofluorescence microscopy. As a consequence of this specific distribution, *E. coli* O157:H7 are present predominantly on the surface of the fecal mass. Sampling the feces and terminal rectum of cattle immediately after slaughter found higher numbers of *E. coli* O157:H7 at the site closer to the rectoanal junction, and low- and high-level carriers were identified. High-level carriage was detected in 3.7% of the animals, and carriage on the mucosal surface of the terminal rectum was associated with high-level fecal excretion. This supports the finding that the mucosal epithelium of the terminal rectum of cattle is an important carriage site for *E. coli* O157:H7, and that high-level fecal shedding of *E. coli* O157:H7 results from colonization of this site.

**Experimental reproduction**

Experimentally, *E. coli* O157:H7 causes fatal ileocolitis in newborn calves under 36 hours of age. Affected calves developed fatal ileocolitis at the site closer to the rectoanal junction and effacing lesions in both the large and small intestines by 18 hours after inoculation. This enrichment step may be followed by immunomagnetic separation with beads coated with *O157*-specific antibody before plating on to agar. Because *E. coli* O157:H7 often occurs in small numbers in bovine feces, immunomagnetic separation is now in common use. Enrichment broths are comparable to each other but are superior to direct plating. In addition, regardless of the culture protocol used, recovery of *E. coli* O157:H7 is more likely from fresh fecal samples than from frozen samples.

**CLINICAL PATHOLOGY**

**Detection in feces**

A review is available of the details of the culture techniques for the detection of *E. coli* O157:H7 in the feces of cattle. A number of culture methods for the screening of fecal specimens for *E. coli* O157:H7 are available but no standard protocol is recommended. Because none of the techniques provides 100% sensitivity, the isolation rates of *E. coli* O157:H7 from bovine feces using only one test will result in an underestimation of the incidence of the organism in bovine feces. Performing more than one test must be considered.

Feces may be directly plated on to selective media and/or differential agars or may be selectively enriched in a variety of broth enrichment protocols followed by plating on to selective agars. This enrichment step may be followed by immunomagnetic separation with beads coated with *O157*-specific antibody before plating on to agar. Because *E. coli* O157:H7 often occurs in small numbers in bovine feces, immunomagnetic separation is now in common use. Enrichment broths are comparable to each other but are superior to direct plating. In addition, regardless of the culture protocol used, recovery of *E. coli* O157:H7 is more likely from fresh fecal samples than from frozen samples.

**PFGE** has been used extensively to investigate the epidemiology of *E. coli* O157:H7, although it has not been evaluated as a tool for establishing genetic relationships. PCR has been used to detect virulence genes and molecular epidemiology of *E. coli* O157:H7 isolates from abattoirs.

A real-time PCR kit for the detection of *E. coli* O157:H7 in bovine fecal samples is commercially available. Both the specificity and sensitivity of the assay are 99% for isolates in pure culture and the assay detects 1 cfu/g of *E. coli* O157:H7 in artificially inoculated bovine feces following enrichment.

The culture of swabs of the rectoanal junction mucosa is as sensitive and may be more sensitive than culture of feces for the detection of *E. coli* O157:H7 in cattle. Because the sample site is the location of *E. coli* O157:H7 colonization, which contains high numbers of the organism. For both experimentally and naturally infected cattle, the rectoanal mucosa predicted the duration of infection. Cattle transiently shedding *E. coli* O157:H7 for less than 1 week were positive by fecal culture only and not by rectoanal mucosa culture, whereas colonized animals were positive early on by rectoanal mucosa junction culture.
Detection in ground beef

A rapid, specific and quantitative method to detect E. coli O157:H7 in ground beef in a combined immunomagnetic separation for cell capture and concentration with real-time PCR has been developed.

CONTROL

In spite of the large amount of information generated about various aspects of E. coli O157:H7 since 1982, reliable management practices to control the infection effectively at all stages of beef production from the farm to the slaughter plant, the retail handling and processing, and finally the consumer, have not been examined scientifically so that recommendations could be made at each stage of production that would result in control of the organism at a very low level. Studying E. coli O157:H7 during the entire cattle-production process is problematic because of the complexity of the system and the complexity of the ecology of the organism. The development of economically feasible intervention strategies that are effective in reducing foodborne pathogens is a priority for both the beef and dairy industries.

The effective control of E. coli O157:H7 will require the implementation of several different infectious disease control strategies and management procedures extending from the farm environment to the meat processing plant, the retail handling and processing of meat products and the handling and cooking of beef products in the home.

The features of the ecology of E. coli O157:H7 that are important to consider in a control program include:

- Lack of a host specificity such that indistinguishable isolates can be found in a variety of species
- Near ubiquitous distribution on cattle farms
- Transient residence in the gastrointestinal tract flora of individual animals that is not associated with disease
- Temporal clustering at the population level such that most fecal shedding is confined to sharp bursts in a high percentage of animals separated by much longer periods of very low prevalence
- A higher prevalence in young animals compared to mature ones
- A higher prevalence in animals with gastrointestinal flora disturbances such as those associated with transit, feed changes, or antimicrobial dosing
- A markedly higher prevalence during warm months
- Molecular subtyping of E. coli O157:H7 indicate that certain subtypes can persist on cattle farms for years, supporting the conclusion that cattle farms represent a reservoir
- New subtypes are periodically found on particular farms, and indistinguishable subtypes can be found on farms separated by hundreds of kilometers even in the absence of any obvious animal movements between them
- Commercial feeds are sometimes contaminated with E. coli O157:H7 and it seems likely that feeds represent an important route of dissemination
- Mixed feeds collected from feeding troughs are commonly positive for E. coli O157:H7, as are water troughs, and feed and water probably represent the most common means of infection
- Environmental replication in feeds and in the sediments of water troughs occurs and may account for the higher level of fecal shedding in the summer months
- Since E. coli O157:H7 has been found to persist in and remain infective for at least 6 months in water trough sediments, this may be an important environmental niche where the organism survives during periods when it cannot be detected, especially during cold months
- Traditional means of controlling infectious diseases, such as eradication or test and removal of carrier animals, do not appear to be feasible
- Certain farm management practices, especially those related to maintenance and multiplication of E. coli O157:H7 in feed and water, may provide practical means to substantially reduce the prevalence of these agents in cattle on farms and in those arriving at slaughter plants
- It is virtually impossible to exclude E. coli O157:H7 from beef-processing plants and carcasses
- Cross-contamination of whole carcasses with fecal-derived bacteria occurs as a result of airborne transmission (during removal of the hide). Contaminated equipment and cross-contamination is inevitable during boning-out and grinding (where portions of carcasses from a large number of animals are commingled or make contact with a common piece of equipment)
- The very small numbers of E. coli O157:H7 predicted to contaminate carcasses under highly effective control could be spread to a large volume of beef product during processing and multiply if the product experienced temperature abuse.

Because the dose of E. coli O157:H7 to cause human illness is very low, this dispersion of the organism throughout a high volume of product may constitute the greatest risk to public health.

The control of E. coli O157:H7 will depend on implementation of management procedures which extend from the farm (preharvest), slaughtering process (postharvest) and retail handling and processing, to ultimately the consumer.

Preharvest beef safety production programs - beef quality assurance programs on the farm

Preharvest beef safety production programs consist of policies, strategies, and procedures that are carried out on food-producing animal farms with the objective of producing safe and wholesome product free of antibiotic or chemical residues and with a minimum of pathogens that could be transferred through meat to humans. Some examples follow here.

The Canadian On-Farm Food Safety (COFFS) Program is a producer-led, industry/government partnership that provides national commodity groups with the opportunity to develop the strategies and the necessary tools to educate producers and to implement national on-farm food safety initiatives consistent with the Codex Alimentarius Hazard Analysis Critical Control Points (HACCP) definitions and principles and with the Canadian Food Inspection Agency's Food Safety Enhancement Program.

The COFFS Program established in May 1997 is funded by a grant from Agriculture and Agri-food, Canada's Canadian Adaptation and Rural Development Fund. Technical advice is provided by the Canadian Food Inspection Agency and the program is administered by the Canadian Federation of Agriculture.

The beef cattle industry in Canada has begun excellent programs with Canadian Cattlemen – Quality Starts Here: Good Production Practices for Cow-Calf Producers and Recommended Operating Procedures for Feedlot Animal Health.

The Canadian Cattlemen's Association has developed a number of quality assurance schemes for the various segments of its industry. The Quality Starts Here program was developed through collaborative discussions with all those along the food chain – cow-calf operators, feedlots, packers, veterinarians, and pharmaceutical companies. The objective was to develop a set of good production practices to deal with sanitation and feeding issues and to minimize problems arising from lesions and bruising at injection sites and from drug residues. It is important to note that this program was developed to improve
the beef supply chain as a whole and to augment the processing industry's in-plant HACCP programs. In part, it attempts to reduce information costs along the supply chain.

Manuals have been produced and distributed to those interested including: Good Practice Guides for cow-calf operators and feedlots and Recommended Operating Procedures for Feedlot Animal Health. The procedures are based on HACCP concepts. At present, the CCA schemes do not include provisions for independent monitoring of cow-calf operations or feedlots. This may be a weakness of the scheme as it may not be accepted by those further along the supply chain (by retailers or the hotels, restaurants, and institutions) and, in particular, export markets. Without independent accreditation, this quality assurance scheme cannot claim to be HACCP-based. If, over time, producers feel that they receive a premium for animals raised according to the specifications of the quality assurance scheme, pressure may increase to have independent verification. The CCA has also endorsed a national animal identification scheme. Technical details still need to be worked out to insure that maximum use can be made of the information. The need for the information to be transferred from the live animal to the carcass remains a technical challenge. However, there is cooperation to find a solution. It is intended that, in the event of an incident that requires traceback, it will be possible with this system to identify the last herd (feedlot, pasture group, etc.) in which the subject animal was located and, from the ear tag, the herd of origin.

Specific strategies for control of Escherichia coli O157:H7 at preharvest level

The literature on preharvest strategies to reduce the carriage and shedding of E. coli O157:H7 in cattle has been reviewed.21,22 A stochastic simulation model was used to assess the benefit of measures implemented in the preslaughter period that are aimed at reducing the contamination of beef carcasses with Shiga-like-toxin-producing E. coli O157:H7.93 Control measures were based on either reducing the herd prevalence of infection, reducing the opportunity for cross-contamination in the processing plant by reordering of the slaughter procedures, reducing the concentration of E. coli O157:H7 in fresh feces or reducing the amount of feces, mud and bedding ('tag') transferred from the hide to the carcass. Simulations suggested that the greatest potential is associated with vaccination and with an agent that reduces shedding of E. coli O157:H7 in feces. An industry-wide reduction in the amount of tag attached to hides and addition of a source of cattle having a prolonged average fasting time were not predicted to have a large impact on mean amount of carcass contamination with E. coli O157:H7.

Animal management strategies

Water systems and runoff

Interventions at the water trough level offer significant potential to reduce E. coli O157:H7 contamination and cross-contamination. Suggested potential strategies to reduce E. coli O157:H7 survival in the water supply include chlorination, ozonization, frequent cleaning, and screens that reduce organic solids in water troughs. However, field studies found that chlorination of water troughs did not alter the prevalence of E. coli O157:H7 in the troughs, or in the feces of cattle in those pens.49

Environmental control of Escherichia coli O157:H7

The survival of E. coli O157:H7 for extended periods of time (weeks to months) in livestock production environments may enable transfer of the organism back to cattle through contaminated feed or water. This creates a cycle of infection allowing E. coli O157:H7 to be maintained in cattle herds. Effective control of E. coli O157:H7 requires suppression at as many points in the cycle of infection as possible in order to reduce its spread. Minimizing contamination of water troughs and feed bunk together with adequate manure management should contribute to a significant reduction in the spread of E. coli O157:H7 in cattle, crops, and water sources.

The fecal prevalence of E. coli O157:H7 among mature dairy cattle is associated with the choice of bedding material used on a farm.48 The use of sawdust for bedding material for lactating dairy cattle through contaminated feed or water. This creates a cycle of infection allowing E. coli O157:H7 to be maintained in cattle herds. Effective control of E. coli O157:H7 requires suppression at as many points in the cycle of infection as possible in order to reduce its spread. Minimizing contamination of water troughs and feed bunk together with adequate manure management should contribute to a significant reduction in the spread of E. coli O157:H7 in cattle, crops, and water sources.

Diet changes

The literature on the effects of dietary manipulation of E. coli populations in cattle has been reviewed.88 Feedlot and high-producing dairy cattle are fed rations with a high percentage of grain. When the starches that escape the ruminal microbial degradation move on to the large intestine, enterohemorrhagic E. coli ferment the sugars and the populations of E. coli increase. Cattle fed grain rations shed larger numbers of E. coli, especially E. coli O157:H7 in barley-fed cattle. When cattle are abruptly switched from a high-grain ration to a forage diet, generic E. coli populations decline by 1000-fold within 5 days. Cattle naturally infected with E. coli O157:H7 shed smaller numbers of the organism when the ration is changed to a forage-based diet compared to cattle fed continuously on a high grain diet.52 However, the magnitude of reduction is highly variable between studies and thus is not currently recommended. Fasting for 48 hours and type of diet prior to fasting has no effect on fecal shedding of E. coli O157:H7 in cattle.48 Thus feed withdrawal prior to slaughter should not increase the risk of the herd of E. coli O157:H7 entering the food chain. However, re-feeding 100% forage following a 48-hour fast results in a significant increase in the number of animals shedding E. coli O157:H7. This may occur when feeder cattle are moved from one farm to another through a sale barn and may be one of the reasons for the higher incidence of E. coli O157:H7 shedding by cattle when they first enter the feedlot.

Proposals aimed at dietary modifications must be balanced with the practical applications of commercial livestock feeding operations.

Direct antipathogen strategies

Several strategies have been examined that specifically target and directly kill pathogenic bacteria. These include: the use of antibiotics; antimicrobial proteins produced by bacteria; bacteriophages; compounds that specifically target the physiology of pathogenic bacteria; and vaccination.

Antibiotics

Some preliminary studies have found that feeding neomycin to cattle for 48 hours reduced the populations of generic E. coli and E. coli O157:H7 in their feces.71 Antimicrobial proteins and bacteriophages

Only limited information is available on their effectiveness.

Vaccination against Escherichia coli O157:H7

There is evidence that virulence factors secreted by the type III system can be used as effective vaccine components for the reduction of colonization of cattle by E. coli O157:H7.93 Vaccination of cattle with proteins secreted by E. coli O157:H7, three times at 3-week intervals,
significantly reduced the numbers of bacteria shed in feces, the numbers of animals that shed and the duration of shedding in an experimental model. Vaccination of cattle also significantly reduced the prevalence of E. coli O157:H7 in a clinical trial conducted in a typical feedlot. The pretreatment prevalence of animals shedding E. coli O157:H7 averaged 30%. The average proportion of cattle shedding the organism in vaccine-treated pens was 8.8%, and in nonvaccinated pens 21.3%. Since the type III secreted antigens are relatively conserved among non-O157 enterohemorrhagic E. coli serotypes, the vaccine formulation might be broadly cross-protective.

Using the pig as an experimental model, pregnant dams were vaccinated with E. coli O157:H7 adhesin ( intim O157) at 2 and 4 weeks before farrowing.64 E. coli O157:H7 adhesin ( intim O157) -specific antibody titers in colostrum and serum of dams were increased after parenteral vaccination. Neonatal piglets were allowed to suck vaccinated dams for up to 8 hours before being inoculated with a Shigatoxin-negative strain of E. coli O157:H7. Piglets that had ingested colostrum containing E. coli O157:H7 adhesin ( intim O157) -specific antibodies from vaccinated dams, but not those nursing sham-vaccinated dams, were protected from E. coli O157:H7 colonization and intestinal lesions. This supports the hypothesis that intim O157 is a potential antigen for E. coli O157:H7 antitransmission vaccine.

A vaccination field trial evaluated the efficacy of E. coli O157:H7 vaccine in a sample of feedlots in Alberta and Saskatchewan.65 Pens of cattle were vaccinated once on arrival processing and again at reimplanting. The E. coli O157:H7 vaccine included 20 µg of type III secreted proteins. Fecal samples were collected from 30 fresh fecal droppings within each feedlot pen at arrival, at revaccination and again at reimplanting. The prevalence of E. coli O157:H7 strains approximately by two logs (10^6 to 10^4) in the rumen and three logs (10^6 to 10^3) in the feces.66

Control of Escherichia coli O157:H7 during slaughtering and postharvest stage

As a result of public concern about E. coli O157:H7, the meat inspection service in many countries has been reorganized to deal with control of the organism in the processing of beef. In the USA, the presence of E. coli O157:H7 in ground beef was declared an adulterant. Surveillance systems have also been established in many countries to obtain more information about the presence of the organism and to report outbreaks, and considerable research has emerged.

Elaborate E. coli O157:H7 detection systems are now in place in abattoirs in many countries as part of the Hazard Analysis of Critical Points System (HACCP) to ensure that contamination of beef carcasses with E. coli O157:H7 is below certain legislated levels.

The surfaces of beef carcass cattle are contaminated with enteric bacteria immediately after removal of the hide during processing following slaughter. Significant correlations between bovine fecal and hide prevalence with beef carcass contamination indicate a role for controlling E. coli O157:H7 in live cattle.18

Major progress has been made in the last decade in the processing of beef carcasses following slaughter to reduce the microbial contamination of beef using the HACCP.

The seven Hazard Analysis of Critical Points System principles

HACCP is a process control system designed to identify and prevent microbial and other hazards in food production.

It includes steps designed to prevent problems before they occur and to correct deviations as soon as they are detected. Such preventive control systems with documentation and verification are widely recognized by scientific authorities and international organizations as the most effective approach available for producing safe food.

In the USA, as of 1996, the US Department of Agriculture (USDA) adopted the Pathogen Reduction HACCP system, which includes four major elements:

- Every plant must adopt and carry out its own HACCP plan, which systematically addresses all significant hazards associated with its products
- Mandatory E. coli testing in slaughter plants. Every plant must regularly test carcasses for E. coli to verify the effectiveness of the plant's procedures for preventing and reducing fecal contamination
- Pathogen reduction performance standards for Salmonella. All plants and plants producing raw ground products must insure that their Salmonella contamination is below the current national baseline
- Sanitation standard operating procedures. Every plant must adopt and carry out a written plan for meeting its sanitation responsibilities. Effective sanitation in slaughter and processing plants is essential to prevent adulteration of meat and poultry products.

HACCP is endorsed by such scientific and food safety authorities as the National Academy of Sciences and the National Advisory Committee on Microbiological Criteria for Foods (NACMCF), and by such international organizations as the Codex Alimentarius Commission and the International Commission on Microbiological Specifications for Foods.

HACCP systems must be based on the seven principles articulated by the NACMCF. The seven principles are: (1) hazard analysis, (2) critical control point identification, (3) establishment of critical limits, (4) monitoring procedures, (5) corrective actions, (6) record keeping, and (7) verification procedures.
The Seven HACCP Principles

- **Principle 1: Conduct a hazard analysis.** Plants determine the food safety hazards and identify the preventive measures the plant can apply to control these hazards.

- **Principle 2: Identify critical control points.** A critical control point (CCP) is a point, step or procedure in a food process at which control can be applied and, as a result, a food safety hazard can be prevented, eliminated, or reduced to an acceptable level. A food safety hazard is any biological, chemical, or physical property that may cause a food to be unsafe for human consumption.

- **Principle 3: Establish critical limits for each critical control point.** A critical limit is the maximum or minimum value to which a physical, biological, or chemical hazard must be controlled at a critical control point to prevent, eliminate, or reduce to an acceptable level.

- **Principle 4: Establish critical control point monitoring requirements.** Monitoring activities are necessary to assure that the process is under control at each critical control point. The Food Safety and Inspection Service (FSIS) requires that each monitoring procedure and its frequency be listed in the HACCP plan.

- **Principle 5: Establish corrective actions.** These are actions to be taken when monitoring indicates a deviation from an established critical limit. The final rule requires a plant's HACCP plan to identify the corrective actions to be taken if a critical limit is not met. Corrective actions are intended to ensure that no product injurious to health or otherwise adulterated as a result of the deviation enters commerce.

- **Principle 6: Establish record keeping procedures.** The HACCP regulation requires that each plant maintains certain documents, including its hazard analysis and written HACCP plan, and records documenting the monitoring of critical control points, critical limits, verification activities, and the handling of processing deviations.

- **Principle 7: Establish procedures for verifying the HACCP system is working as intended.** Validation insures that the plans do what they were designed to do, i.e. that they are successful in insuring the production of safe product. Plants will be required to validate their own HACCP plans.

HACCP is a system that identifies potential food safety risks, prevents or corrects them, records what was done and verifies that the system works. The objective is to improve food safety for meat and poultry. It is assumed that a reduction in carcass contamination leads to a proportionate reduction in illness and death. Pathogens can contaminate meat and poultry at any step from the processes used to produce them that include final food preparation and handling.

Postharvest decontamination techniques

- **Steam pasteurization.** The commercialization of the steam pasteurization system has been successful and it is used in many large beef slaughter facilities in North America. Hot water/steam vacuum systems are designed to remove visible spots of contamination from small areas on the carcass and are used to augment the traditional knife trimming. Steam pasteurization is a process whereby beef carcasses are placed in a slightly pressurized, closed chamber at room temperature and sprayed with steam that blankets and condenses over the entire carcass. This raises the surface temperature to 195°F or 200°F and kills nearly all pathogens. Carcasses then are sprayed with cold water.

- **Steam vacuum.** Steam or hot water is sprayed on a beef carcass followed by vacuuming, which has the combined effect of removing and/or inactivating surface contamination. The hand-held device includes a vacuum wand with a hot water spray nozzle, which delivers water at approximately 82–88°C to the carcass surface, as well as steam vacuuming. Steam vacuuming is approved for use by the USDA-FSIS as a substitute for knife trimming for removing fecal and ingesta contamination when such contamination is less than 2.54 cm at its greatest dimension.

- **Chemical rinses.** Organic acids are typically applied as a rinse to the entire surface of the carcass. The USDA-FSIS approved the use of organic acid solutions such as acetic, lactic, and citric acids at concentrations of 1.5–2.5%. Acetic and lactic acids have been most widely accepted as carcass decontamination rinses. The effectiveness of organic acids is best achieved shortly after hide removal, when the carcass is still warm.

**Progress made with decontamination processes**

The multiple decontamination processes, as applied in actual plant settings, have resulted in significant improvements in the microbiological quality of beef. There is considerable evidence to support the effectiveness of in-plant application of multiple decontamination technologies (hurdle technology). Reductions were achieved from 43% of lots sampled pre-incubation as positive for E. coli O157:H7 to 1.9% remaining positive postprocessing after multiple decontamination methods on the slaughter floor.
In February 2005, the beef industry welcomed news from the USDA-FSIS showing a significant drop in E. coli O157:H7 prevalence in 2004, as compared to 2003. The FSIS data showed that the percentage of E. coli-O157:H7-positive ground beef samples collected in 2004 fell by 43.3% compared with the previous year. The data showed that, between 2000 and 2004, the percentage of positive samples of E. coli O157:H7 had declined by more than 80%. FSIS also reported that there were six recalls related to E. coli O157:H7 in 2004 compared to 12 in 2003 and 21 in 2002. This is very good news for consumers and all sectors of the beef industry and represents the coordinated efforts to reduce this pathogen throughout the beef production chain, from farm to kitchen. The Beef Industry Food Safety Council (BIFSCo), which is funded by beef producers with checkoff dollars, directs a Board's contractors for checkoff-funded programs. Following the E. coli summit in January 2003, BIFSCo worked to compile best practices from across the beef industry. Through this effort, all sectors of the beef industry have worked collectively toward the goal of improving safety— from cow-calf producers and feedlot operators to packers and processors, to retailers and foodservice providers. The best practices were completed and distributed throughout the industry.

In addition, checkoff-funded research continues to show promise for interventions such as thermal pasteurization, feed additives, and animal carcass washes that eliminate or reduce pathogen presence.

**Irradiation**

Irradiation of beef in the postharvest stage is a process which could be used to inactivate pathogens. At the present time, the percentage of beef being irradiated is very small. Constraints include reluctant consumer acceptance of radiation-treated food, increased price of production, and the irradiation's negative effect on odor and flavor.

**Consumer education on handling and cooking meat**

To prevent infection with E. coli O157:H7, consumers must be encouraged to follow four simple steps: Chill promptly. Clean hand and kitchen surfaces. Separate, don't cross-contaminate; and Cook thoroughly.

**Visitors to animal farms**

Farm animals and the farm environment present a variety of possible sources of infection with E. coli O157:H7. Farm visits are popular among city families for holidays and family gatherings, and schools in urban areas frequently promote educational farm visits for their students. The consumption of unpasteurized milk by visiting children and close physical contact with animals have been documented as most likely sources of infection in some outbreaks of E. coli O157:H7 infection. Farm animals and the farm environment present a variety of possible sources of infection. Visitors to animal farms, especially groups such as schoolchildren, must avoid petting animals whose hair coats and skin may harbor E. coli O157:H7.69 Verotoxin-producing E. coli of bovine origin can infect humans in the farm environment. Many dairy-farm residents regularly consume unpasteurized milk, a potential source of E. coli O157:H7. Using geographical information system mapping and modeling, studies in Canada have clearly identified a relationship between an increased risk of verotoxin-producing E. coli infections and disease among rural populations and cattle density.70

**REFERENCES**

decrease in the diversity of coliforms in the individual piglet. Different strains of E. coli were predominant in different animals, which may in turn facilitate the spread of pathogenic strains.

**Escherichia coli in pigs**

Many strains are nonpathogenic. Pathogenic E. coli can be divided into a variety of pathotypes but there are three major types. These are enterotoxigenic E. coli, verotoxin-producing E. coli and attaching and effacing E. coli. There are two major complicating factors in pigs: one of these is that the intestine has different distributions of receptors with changing age. The other is that nearly all isolates (94.8%) that carry the enterotoxin genes also carry genes for one of the fimbrial adhesins.

The two most prominent genotypes are K88, LTA, STa, STb, F18, STa, STb, SLT.

**Enterotoxigenic Escherichia coli**

These have two major virulence factors: (a) adhesins or fimbriae and (b) enterotoxins. The adhesins promote or control the adherence to small intestinal epithelial cells and include K88, K99, F18, and STa. Only F18 and K88 are frequently associated with disease in weaned pigs. Only young pigs are susceptible to K99 or F187P. Age-related susceptibility is related to the presence or absence of the appropriate receptors in the small intestine. The enterotoxins belong to two groups; heat-labile enterotoxin (LT) and the heat-stable enterotoxins STa and STb. Only weaned pigs are susceptible to F18 and resistance develops by 8 weeks of age, as the binding appears to be blocked. The receptor for F18 has not yet been identified but it is a glycoconjugate in which the attached carbohydrate acts as a target for the fimbriae. The F18 adherence occurs in two forms: ab (found in enteropathogenic E. coli), STa or STb (found in enterotoxigenic E. coli). There is also an F4 fimbrial antigen which is on a different chromosome from F18. F4 enterotoxigenic E. coli cause problems in the first week after weaning but F8 verotoxin-producing E. coli cause problems 1-2 weeks after weaning.

**Verotoxin-producing Escherichia coli**

These strains produce Shiga toxin or Shiga-like toxins (verocytotoxins) and cause edema disease. Swine verotoxin-producing E. coli colonize the intestine via the F18 pilus, as do some swine enterotoxigenic E. coli. It is not uncommon to find F18-positive strains that produce enterotoxins and verotoxins and can cause both diarrhea and edema disease.

**Attaching and effacing Escherichia coli**

These bacteria possess the eae gene, which encodes for intimin, which is an adhesin factor that facilitates the attachment of bacteria to intestinal epithelial cells. It is on a plasmid that is distinct from the K88-encoding plasmid in enteropathogenic E. coli and enterotoxigenic E. coli strains that produce attaching and effacing lesions. The following strains are found:

- K88, ab, ac, ad
- F18ab (more associated with edema disease); F18ac
- F41, usually associated with K99
- Fimbrinae
- Strains containing STa, STb, STb (Shiga-like toxin 2e(STx2e), and possibly enterocoaggregative E. coli.

Twenty years ago most of the pig strains were Stx2e and F18 were rare then but are common now.

**O157 in pigs**

In a recent survey in Sweden only two O157:H7-positive and four O157:H7-negative strains have been described. The O157:H7-positive strains have been described. Pathogenicity is indicated by genes encoding for one or more of the Shiga toxins but several other factors may also be necessary. Most strains do not possess Shiga toxins but do carry the F4 or F18 fimbrial adhesins. A third of strains produced STa or STb but less than a third produce STx and half the eae gene.

**Postweaning diarrhea and edema disease**

are two common causes of disease in weaned pigs. In postweaning diarrhea, there is diarrhea, dehydration, and often death. In edema disease or enterotoxemia there is subcutaneous edema of the forehead and eyelids, and neurological clinical signs such as ataxia, convulsions, recumbency, and death. Enterotoxigenic E. coli strains isolated from cases of postweaning diarrhea mainly belong to O groups O8, O141, O147, O149, and O157. Strains associated with edema disease predominantly have O groups O138, O139, or O141. Postweaning diarrhea is a significant cause of mortality between weaning and marketing in some herds. Although the clinical signs in these two diseases are different, they occur in similar age groups and the same type of management change may precede their occurrence. Weaning and weaning age are both associated with significant effects on the microbial populations. In postweaning diarrhea the bacteria disappear more quickly, usually by about 7 days postinfection, but in edema disease may still be there 9 days postinfection but with a slower buildup to a peak within 3-5 days postinfection. A typical scenario would be severe diarrhea occurring 4-5 days postweaning followed by clinical edema disease with mortality reaching as high as
50%. Both are associated with the proliferation of predominantly hemolytic serotypes of *E. coli* within the small intestine. However, it is rare to encounter both diseases concurrently on the same farm. In postweaning diarrhea the serotypes are enterotoxigenic and the major manifestation is diarrhea resulting from enterotoxin activity at the time of proliferation. In edema disease non-enterotoxigenic strains produce a verotoxin that, after a period of time, indirectly produces the neurological syndrome characteristic of this disease.

One of the features of virulence in *E. coli* is the presence of mobile genetic elements such as plasmids, bacteriophages, and pathogenicity islands. A pathogenicity island coding for F18-positive fimbriae has been found. 14 Cytotoxins distending toxins have also been described. 13 In many countries the prevalence of edema disease has decreased markedly during the past decade, whereas that of coliform gastroenteritis has increased. It is possible that this change reflects the trend towards earlier weaning of pigs, although the emergence and spread of new enterotoxigenic strains may also be a factor. More recently a third disease, cerebrospinal angiopathy, has been attributed to the effects of infection with *E. coli*. Although there are some similarities in the etiology and epidemiology of these diseases they are sufficiently different to warrant a separate description. One of the major features in common is the process of weaning, probably the most serious disturbance a young piglet may face. It alters immune functions and produces stress. 16 It also profoundly alters the intestinal microflora 17,18 particularly the coliform flora. 19 Some strains may increase but others may decrease.

**EDEMA DISEASE (GUT EDEMA, ESCHERICHIA COLI ENTEROTOXEMIA)**

Edema disease occurs in weaner and grower pigs and is characterized by subcutaneous and subserosal edema, progressive ataxia, recumbency, and death.

### Lesions

Facial edema, full stomach and mesenteric edema

### Diagnostic confirmation

Culture specific organism

### Differential diagnosis list

- Pseudorabies
- Viral encephalomyelitis of pigs
- Encephalomyocarditis
- Streptococcal meningitis
- Salt poisoning
- Organic arsenic poisoning
- Mulberry heart disease

### Treatment

None

### Control

Avoid drastic changes in diet

**ETIOLOGY**

Edema disease is associated with *E. coli* strains producing a verocytotoxin type II variant (VT2e), and Shiga-like toxin (SLT2e), and belonging to one of the three serogroups that cause edema disease: 0138, 0139, or 0141. 20 The biochemical phenotypes were studied in Sweden and each of the O138, O139, and O141 serotypes is dominated by one phenotypic type even though others do occur within the serotype. 21 The entire pathogenicity island known as ETI2 is necessary for the edema disease virulence factors in O138, O139, or O141. 22 Isolates of *E. coli* have been found in which the toxin or F18 fimbrial types were not related to selected electrophoretic types which suggests that toxin and F18 genes in the isolates from pigs with postweaning diarrhea or edema disease occur in a variety of chromosomal backgrounds. 23 The bacteria colonize the small intestine without causing significant changes by means of the adherence factor F18 (F107). 24 The *E. coli* strains with the highest mucin-binding capacity belonged to potential ST toxin producers, whereas strains without genes encoding for toxin production displayed much weaker binding to mucin capacity. 25 In a recent outbreak in Denmark, where edema disease had not previously been observed, most isolates were of serotype O139 but a few isolates could not be typed by O serotyping. 26 All the isolates from the Danish pigs with edema disease grouped together in one cluster, in contrast to isolates from other countries, which did not form any clusters. In Denmark 563 isolates were serotyped 27 and O149 was found in 49.9% of the isolates, O138 in 14.9%, O139 in 6.9%, O141 in 4.1%, and O8 in 3.7%. The virulence genes were examined and they fell into six pathotypes, which contained 65.7% of all isolates. 27 The F107 fimbriae are a major colonization factor in *E. coli* that cause edema disease. 28,29 The serotypes of *E. coli* isolated from piglets with diarrhea, piglets with edema disease, and healthy piglets have been reported. 30,31

The inheritance of susceptibility to edema disease has been examined. 32,33 Inheritance of resistance to intestinal colonization with *E. coli* causing edema disease is thought to be under the control of one locus consisting of two alleles with susceptibility (S)-dominating resistance (R). 32 Genetic susceptibility to edema disease is due to the ability of F107-expressing *E. coli* to adhere to and colonize intestinal brush border cells, and not due to toxin susceptibility. There is a high correlation between intestinal F18 receptor genotype and susceptibility to disease 34 but pigs with resistant F18 receptor genotypes were not entirely protected against colonization by *E. coli*.

**EPIDEMIOLOGY**

The specific serotypes of *E. coli* that are capable of causing the disease are introduced into a piggery and become part of the normal intestinal flora. They may not cause disease until a particular set of environmental conditions arise, when they proliferate excessively within the intestine to produce toxin. The disease occurs predominantly in pigs between 4 and 12 weeks of age. It may occur sporadically but more commonly occurs as an outbreak affecting up to 50% of the pigs within the group. Characteristically the larger and faster-growing pigs within the group are affected. The disease is not common in runt or poorly thriving pigs. Age at weaning, diet, overcrowding, chilling, transportation and other factors influence the susceptibility of pigs to *E. coli* producing SLTII and could determine whether subclinical or clinical edema disease occurs following infection. Piglets fed high-protein diets are more susceptible to experimental clinical edema disease than piglets fed low-protein diets. 35 The disease frequently occurs within 1 week following a change in diet or *ad libitum* feeding but may also follow such factors as weaning, vaccination, pen change, and regrouping. A study even found verotoxin-producing *E. coli* O139 in water storage tanks and drinking water. 36 One of the observations on F18 fimbriae is that they have increased greatly since 1997 from 10% to 70% and this may be tied into the genetic selection of the stress gene. 37

The outbreak is sudden in onset but short-lived, averaging 8 days and seldom exceeding 15 days. The epidemiology of the disease in affected herds is not characteristic of a highly contagious disease and it does not usually spread to involve other pens of pigs on the same farm.

The disease follows proliferation of the relevant serotypes within the intestine.
Serotypes of *E. coli* associated with gut edema may be isolated from the feces of healthy pigs. The factors initiating proliferation are unknown but changes in the composition or amount of diet commonly precipitate the onset. Management factors that potentiate oral–fecal cycling of these organisms are likely to be of importance in spread within the group.

**PATHOGENESIS**

It is a simple progression. The intestine of a susceptible pig, which is usually fast-growing and without maternal antibody, has receptors for F18 pili. This appears to be the major factor, and then colonization by *E. coli* occurs with toxin production, absorption of toxin, and damage to vascular epithelium. The endothelium appears to have a specific toxin receptor for Stx2e and finally edema develops in target tissues.

Nutritional factors and gastrointestinal stasis result in proliferation of the *E. coli* strains in the small intestine and toxin production. There is generally a delay between the initial period of maximal intestinal proliferation of the organism and the onset of clinical signs. In the experimental disease, clinical signs occur 5–7 days following initial oral challenge with bacteria and up to 36 hours following intravenous inoculation with toxin. The delay appears to be related to the development of vascular lesions, with increased vascular permeability leading to edema formation and encephalomalacia. The experimental oral inoculation of the edema-disease-producing *E. coli* results in colonization of the organisms in the small intestine, and lesions of the vessels of the intestinal mucosa are detectable as early as 2 days after infection. An experimental model for subclinical edema disease in weaned pigs has been described. Microscopic vascular lesions were found in pigs 14 days after oral inoculation with a SLT2-positive strain of *E. coli*. Once postweaning diarrhea occurs there is an increased intestinal permeability that predisposes to edema disease and once edema disease has developed the influx of SLT toxin into the bloodstream is facilitated further, thus precipitating the disease. Edema disease is associated with metabolic acidosis, which might be explained by endogenous acid production, and small-intestinal acidosis. Intestinal acidosis is known to cause mucosal hyperexcitability.

**CLINICAL FINDINGS**

The disease occurs sporadically and unexpectedly in a group, often affecting a number of pigs within a few hours, and shows no tendency to spread from group to group. The thriftiest pigs are most likely to be affected and, once the diagnosis is made, all pigs in the pen should be examined in an attempt to detect other animals in the early stages of the disease. The incidence in a litter will vary up to 50% or more.

The earliest and most obvious sign is incoordination of the hindlimbs, although this may be preceded by an attack of diarrhea. The pig has difficulty in standing and sways and sags in the hindquarters. There is difficulty in getting up and in getting the legs past each other when walking because of a stiff, stringhalt-like action affecting either the forelegs or hindlegs. In some cases there are obvious signs of nervous irritation manifested by muscle tremor, aimless wandering, and clonic convulsions. Complete flaccid paralysis follows.

On close examination, edema of the eyelids and conjunctiva may be visible. This may also involve the front of the face and ears and cannot usually be seen until necropsy. The voice is often hoarse and may become almost inaudible. Blindness may be apparent. The feces are usually firm and rectal temperatures are almost always below normal. The course of the disease may be very short, with some pigs being found dead without signs having been observed. In most cases, illness is observed for 6–36 hours, with a few cases being more prolonged. Recovery does sometimes occur but some degree of incoordination may persist.

**CLINICAL PATHOLOGY**

As an aid to diagnosis, while affected animals are still alive, fecal samples should be cultured to determine the presence of hemolytic *E. coli*. Knowledge of the drug sensitivity of the organism may be important in prescribing control measures. The edema disease principle is cytotoxic to Vero cells and may be useful in an assay system for diagnosis. The toxin Stx2e has been detected in the peripheral circulation of pigs which cause ataxia and recumbency. These include pseudorabies, viral encephalomylitis (Teschner’s disease), encephalomyocarditis, streptococcal meningoencephalitis, salt poisoning, and organic arsenic poisoning. Mulberry heart disease and encephalomyocarditis can produce similar signs, and differentiation on necropsy findings and histopathology is necessary. In poisoning by *Amaranthus spp.* and *Chenopodium album* the signs may be roughly similar but the edema is limited to the perirenal tissues.

**DIFERENTIAL DIAGNOSIS**

Although there are a number of diseases of pigs in the susceptible age group in which nervous signs predominate, gut edema is usually easy to diagnose because of the rapidity with which the disease strikes, the number of pigs affected at one time, the short duration of the outbreak, and the obvious edema of tissues. Affected pigs are usually in prime condition. The ataxia and recumbency must be differentiated from diseases of the nervous system of pigs which cause ataxia and recumbency. These include pseudorabies, viral encephalomylitis (Teschner’s disease), encephalomyocarditis, streptococcal meningoencephalitis, salt poisoning, and organic arsenic poisoning. Mulberry heart disease and encephalomyocarditis can produce similar signs, and differentiation on necropsy findings and histopathology is necessary. In poisoning by *Amaranthus spp.* and *Chenopodium album* the signs may be roughly similar but the edema is limited to the perirenal tissues.

In poisoning by *Amaranthus spp.* and *Chenopodium album* the signs may be roughly similar but the edema is limited to the perirenal tissues.

**TREATMENT**

Treatment is ineffective. Elimination of the toxin-producing bacteria may be attempted by use of antimicrobials in the feed or water supplies. The choice of antimicrobial will vary depending on area variations of the drug sensitivities of *E. coli*. The feed consumption of the unaffected pigs in the group should be reduced immediately and then gradually returned to previous levels over a period of a few days.

**CONTROL**

Pigs should be kept on the same creep feed for at least 2 weeks after weaning.
and the change in feed should be made gradually over a 3-5-day period. Feed restriction through the critical period is frequently practiced and may reduce the occurrence of gut edema. Similarly an increase in crude fiber and decrease in nutrient quality of the diet through this period may reduce the incidence. However, it is evident that a severe restriction and marked decrease in nutrient quality is required to fully achieve this effect and this is not compatible with the purpose of growing pigs. It is essential that pigs on restricted intakes be provided with adequate trough space to allow an even intake of food among the group. For similar reasons, litters of pigs that are batched at or after weaning should be divided into groups of approximately equal body weight.

The strategic incorporation of an antimicrobial into the feed during the risk period may be necessary on some farms. A reduction in the potential for oral–fetal cycling of organisms in the group may reduce the incidence of gut edema. A reduction in the age of weaning may also reduce the incidence. Both organic acids and medication with 50 ppm of enrofloxacin are useful in controlling and/or preventing postweaning edema disease.35

Treatment with anti-VT2E serum can provide protective immunity against edema disease in pigs.45

No vaccine is available. Only vaccines with the preformed fimbriae induce protection and this is limited to the homologous variant6 but, experimentally, vaccination of piglets with a genetically modified Shiga-like toxin 2e prevents edema disease following challenge with the Shiga-like toxin after weaning.19 The concentration of protein in the diet also influenced susceptibility to edema disease. Pigs fed a low-protein diet and not vaccinated developed subclinical edema disease. Pigs fed a high-protein diet and not vaccinated developed clinical edema disease. Pigs fed a high-protein diet and vaccinated had a reduction in the incidence of subclinical edema and did not develop clinical edema disease.

**ETIOLOGY**

The disease is associated with enterotoxicogenic strains of *E. coli* that produce adhesion factors that allow colonization of the intestine and enterotoxins that induce the intact intestinal mucosa to secrete fluid. A summary would be that postweaning diarrhea is associated with enterotoxigenic *E. coli* strains lacking. Of the new strains, which correspond to O149:H10, 92% code for labile toxin (LT) and/or Shiga toxin A and B (STa or STb). Toxin and F18 fimbrial genes in *E. coli* isolated from pigs with postweaning diarrhea or edema disease occur in a variety of chromosomal backgrounds.3

Most commonly, O groups 8, 139, 141, and 149 are associated with the disease.23 Most appear to be O149:STaSTbLT:F4(F88). The strains of O149 isolated in recent years from weaned pigs with diarrhea possess the gene for an additional enterotoxin STa, which older strains lack. Of the new strains, which correspond to O149:H10, 92% code for this gene.4 This enterotoaggregative *E. coli* heat-stable enterotoxin 1 (EST1) gene is found in isolates from weaned pigs that have diarrhea or edema disease.5 The FI07 fimbriae can be found in association with postweaning diarrhea isolates4–7 and other adhesin fimbriae such as Av24 and 2134P have been described.8 Many enterotoxigenic *E. coli* isolates colonize the small intestine of weaned pigs but lack known colonization factors.9,10 The

**REFERENCES**

**POSTWEANING DIARRHEA OF PIGS (COLIFORM GASTROENTERITIS)**

Postweaning diarrhea occurs commonly within several days after weaning and is characterized by reduced growth rate associated with alterations in the mucosa of the small intestine and, in some pigs, by acute coliform gastroenteritis characterized by sudden death, or severe diarrhea, dehydration, and toxemia. It is a major cause of economic loss from both mortality and inferior growth rate for some instances the postweaning diarrhea or edema disease occur in a variety of chromosomal backgrounds.7

Most commonly, O groups 8, 139, 141, and 149 are associated with the disease.23 Most appear to be O149:STaSTbLT:F4(F88). The strains of O149 isolated in recent years from weaned pigs with diarrhea possess the gene for an additional enterotoxin STa, which older strains lack. Of the new strains, which correspond to O149:H10, 92% code for this gene.4 This enterotoaggregative *E. coli* heat-stable enterotoxin 1 (EST1) gene is found in isolates from weaned pigs that have diarrhea or edema disease.5 The FI07 fimbriae can be found in association with postweaning diarrhea isolates4–7 and other adhesin fimbriae such as Av24 and 2134P have been described.8 Many enterotoxigenic *E. coli* isolates colonize the small intestine of weaned pigs but lack known colonization factors.9,10
serogroups of *E. coli* isolated from pigs with postweaning diarrhea in piggeries in Spain include strains that produce the enterotoxigenic *E. coli* and verotoxin-producing *E. coli* and cytotoxic necrotizing factor toxins. The disease can be reproduced consistently in weaned pigs, provided the pig’s epithelial cell brush borders are susceptible to the adhesion of strains of *E. coli* with fimbrial antigen F4 (K88). The DNA sequences coding for the F18 fimbrial antigens and AIDA adhesion are on the same plasmid in *E. coli* isolated from the cecum. Usually they were LTSTb or STb(13%) and 12% were hemolytic and F18-positive. The remainder were nonhemolytic, belonging to the K88 serogroup.

Although there is an etiological similarity between postweaning diarrhea and neonatal enteric colibacillosis in suckling piglets, the relationship is not exact. Strains associated with neonatal enteric colibacillosis may not have the ability to produce postweaning diarrhea and many strains isolated from coliform gastroenteritis lack K88* antigen.

Cytotoxic necrotizing factor (CNF) strains of *E. coli* have been isolated from weaner pigs with necrotic enteritis in South Africa.

Some non-enterotoxigenic O45 isolates of *E. coli* associated with postweaning diarrhea produce attaching and effacing lesions, and their proliferation may be associated with diet. Dual infection with attaching and effacing and enterotoxigenic *E. coli* may also be associated with postweaning diarrhea.

Infection with rotavirus may be an etiological factor. The rotavirus may infect and destroy villous epithelial cells of the small intestine, which may allow colonization of the *E. coli*. Experimentally, a high nutrient intake fed three times daily to piglets weaned at 3 weeks of age produced the most prolonged diarrhea, colonization of the intestine by hemolytic enteropathogenic *E. coli* and persistent shedding of rotavirus. However, other observations cast doubt on the importance of rotaviruses as a cause of the diarrhea because rotaviruses may be found in the feces of pigs without diarrhea a few days after weaning. The acute disease can be reproduced using K88* *E. coli* strains without concomitant infection with rotavirus.

**EPIEDEMOLOGY**

Postweaning diarrhea occurs predominantly in pigs 3–10 days after they are weaned. There is considerable variation in the morbidity and mortality between groups, rooms of pigs and buildings. Most outbreaks are in early weaned pigs. Most commonly, pigs are first observed sick or dead on the fourth or fifth day. The spread within affected groups is rapid and a morbidity rate of 80–90% of the group within 2–3 days is not uncommon. Frequently, other pens of susceptible pigs within the same area will also develop the disease within a short period of the initial outbreak. The problem may persist within a herd, affecting successive groups of weaned pigs over a period of weeks or months. The onset of the problem may be heralded by affected groups of weaned pigs associated with the introduction of a different batch or formulation of the feed. The case fatality rate may be as high as 30% and survivors may subsequently show a reduced growth rate. The weaning of piglets at 3 weeks of age is commonly followed in a few days by a postweaning reduction in growth rate, variations in total dietary intake and the development of diarrhea. Piglets weaned at 3–4 weeks of age into an uncomfortable unsanitary environment appear especially susceptible.

The proliferation of *E. coli* in the intestine following weaning appears secondary to some underlying gastrointestinal disturbance. After weaning there is a progressive increase in viscosity of the intestinal contents, which alters the intestinal structure and growth and stimulates the proliferation of enterotoxigenic *E. coli* in newly weaned pigs. In all groups of pigs examined the number of serotypes or diversity of intestinal flora was reduced in the first week after weaning. The disease is associated with an earlier, more prolonged and greater proliferation of enterotoxigenic *E. coli* in the small intestines than occurs in healthy pigs after weaning. Some studies have shown that susceptibility to adhesion with K88* enterotoxigenic *E. coli* is a requirement for the production of the disease. Experimentally, pigs that did not have the adhesin receptor did not develop diarrhea when challenged with K88* *E. coli* and when in the same environment as the adhesin-positive pigs.

It is believed that several factors commonly associated with weaning predispose pigs to postweaning diarrhea associated with enterotoxigenic *E. coli*. Some of these risk factors include:

- Stress from loss of maternal contact
- Introduction to strange pens and penmates
- Inadequate ventilation in the weaning pens
- Reduction in ambient temperature
- Change in diet
- Cessation of lactation
- Decreased gastrointestinal activity attributable to a temporary increase in gastric pH

- Preweaning exposure (creep feeding) to the dietary antigens fed after weaning.

Hand-washing and donning clean outerwear did not prevent the transmission of *E. coli* but showering and donning clean outerwear did prevent transmission.

Experimentially, there is some evidence that the stress of cold ambient temperature (15°C) can result in a greater incidence of diarrhea in weaned pigs than in those housed at 30°C.

The nature and the amount of the diet that the piglet consumes before and after weaning may be a predisposing factor. One hypothesis suggests that a transient hypersensitivity of the intestine may occur if piglets are primed by small amounts of dietary antigen before weaning, by creep feeding, followed by ingestion of greater quantities of the diet after weaning. Pigs that develop diarrhea tend to be those that consume more food after weaning than their contemporaries.

In general, weaning at 3 weeks of age is associated with alterations in the villous epithelium of the small intestine that result in varying degrees of malabsorption and a reduction in daily growth rate that may last for 2 weeks. There are large rapid reductions in intestinal lactase activity, which coincide with reductions in growth rate and a reduced ability to absorb xylose. There is a reduction in villus height and an increase in crypt depth in the small intestine but these alterations are not necessarily associated with the consumption of creep feed before weaning, which does not support the hypothesis that hypersensitivity to a dietary antigen caused by priming prior to weaning is a factor. There is now considerable doubt about the validity of the intestinal hypersensitivity hypothesis. Recent experimental work indicates that creep feeding is not required for the production of the diarrhea and does not induce morphological changes characteristic of an allergic reaction in the small intestine. The presence of nondigested food in the gut lumen facilitates proliferation of enterotoxigenic *E. coli*. Proteins of animal origin may provide some protection.

Dietary manipulation can modify several changes that normally occur in the small intestine of the piglet after weaning. Feeding a sow milk replacer or a diet based on hydrolyzed casein reduces the increases in crypt depth and the reductions in brush border enzymes. The use of an antibiotic to suppress the microbial activity does not alter the changes in the mucosa after weaning. Pigs that consume more food after weaning have an increased susceptibility to adhesion with *E. coli* and do not induce morphological changes characteristic of an allergic reaction in the small intestine. Dietary antigen before weaning, by creep feeding, followed by ingestion of greater quantities of the diet after weaning. Pigs that develop diarrhea tend to be those that consume more food after weaning than their contemporaries.

The period of the initial outbreak. The problem may persist within a herd, affecting successive groups of weaned pigs over a period of weeks or months. The onset of the problem may be heralded by affected groups of weaned pigs associated with the introduction of a different batch or formulation of the feed. The case fatality rate may be as high as 30% and survivors may subsequently show a reduced growth rate. The weaning of piglets at 3 weeks of age is commonly followed in a few days by a postweaning reduction in growth rate, variations in total dietary intake and the development of diarrhea. Piglets weaned at 3–4 weeks of age into an uncomfortable unsanitary environment appear especially susceptible.

The proliferation of *E. coli* in the intestine following weaning appears secondary to some underlying gastrointestinal disturbance. After weaning there is a progressive increase in viscosity of the intestinal contents, which alters the intestinal structure and growth and stimulates the proliferation of enterotoxigenic *E. coli* in newly weaned pigs. There is a reduction in villus height and an increase in crypt depth in the small intestine but these alterations are not necessarily associated with the consumption of creep feed before weaning, which does not support the hypothesis that hypersensitivity to a dietary antigen caused by priming prior to weaning is a factor. There is now considerable doubt about the validity of the intestinal hypersensitivity hypothesis. Recent experimental work indicates that creep feeding is not required for the production of the diarrhea and does not induce morphological changes characteristic of an allergic reaction in the small intestine. The presence of nondigested food in the gut lumen facilitates proliferation of enterotoxigenic *E. coli*. Proteins of animal origin may provide some protection.

Dietary manipulation can modify several changes that normally occur in the small intestine of the piglet after weaning. Feeding a sow milk replacer or a diet based on hydrolyzed casein reduces the increases in crypt depth and the reductions in brush border enzymes. The use of an antibiotic to suppress the microbial activity does not alter the changes in the mucosa after weaning. Pigs that consume more food after weaning have an increased susceptibility to adhesion with *E. coli* and do not induce morphological changes characteristic of an allergic reaction in the small intestine. Dietary antigen before weaning, by creep feeding, followed by ingestion of greater quantities of the diet after weaning. Pigs that develop diarrhea tend to be those that consume more food after weaning than their contemporaries.
been examined. Gastric pH is higher in weaned pigs and may not reach a level sufficient to prevent significant numbers gaining access to the small intestine. This factor can be of importance in pigs weaned in pens where oral-fecal cycling of E. coli may provide a massive challenge. After weaning, the hemolytic enterotoxigenic E. coli serotype O149:K93, K88a,c (Abbotsown strain) commonly colonizes the rostral small intestine from lower down the intestinal tract. This serotype was also never found in the gastric contents of weaned pigs. When this serotype is present it tends to dominate the E. coli flora at all levels of the intestine. While rotaviruses are common in the intestinal contents of weaned pigs, the presence of the virus is not necessary for production of the disease.

The loss of lactogenic immunity at weaning may be a risk factor. Milk from sows whose progeny develop postweaning diarrhea contain antibodies capable of neutralizing the enterotoxigenic effect of the homologous E. coli. This suggests that the presence of antibody-mediated activity against enteropathogenic E. coli may be important in preventing the disease during the nursing period. At weaning this protection is removed and the piglet is unable to produce its own antibodies rapidly enough to prevent the disease. The stress of weaning does not appear to affect the immune mechanisms of the pig.

The weaning of piglets at birth or 1 day old is associated with a high mortality rate due to diarrhea and septicaemia. The high mortality rate is associated with a lack of colostral antibodies and the strict hygienic conditions required for the artificial rearing of pigs weaned at birth.

**PATHOGENESIS**

The colonization and proliferation of E. coli in the small intestine originates from organisms in the lower part of the intestinal tract. Serotypes of E. coli associated with postweaning diarrhea may be found in the feces of healthy pigs. The virulence factors for postweaning diarrhea are associated with the F4 and F18 fimbrial antigens that carry the genes for the production of toxins (Sta, Stb, L1, SL12a, SL22e). The F18ab variant is expressed by E. coli O139 strain producing Shiga-like toxin and causing edema disease. The F18ac fimbrial E. coli strains often relate to serogroup O141 or O157 and cause diarrhea by expressing enterotoxins (Sta or Stb) either together or with or without Shiga-like toxins. Following weaning, their numbers in feces normally increase markedly even in pigs that remain healthy. The E. coli proliferate in the small intestine and produce an enterotoxin that causes a net loss of fluid and electrolytes to the lumen and subsequent diarrhea. After weaning the net absorption of fluid and electrolytes in the small intestine of pigs is temporarily decreased.

The number of hemolytic E. coli present in the proximal portion of the jejunum may be 10^3-10^5 times higher in affected pigs than in weaned pigs of the same age that do not show signs of disease. The susceptibility of the small intestine to the enterotoxin varies according to the area: the upper small intestine is highly susceptible and susceptibility decreases through the more distal portions. Unlike many other species, the weaning pig depends largely on its large intestine for absorption of fluid and electrolytes with only small changes in net fluid movement occurring along the jejunal and ileal segments. In fatal cases, death results from the combined effects of dehydration and acidosis resulting from fluid and electrolyte losses. In the peracute and acute forms of the disease, there is a shock-like syndrome with marked gastric and enteric congestion, hemorrhagic enteritis, and death.

The experimental model of the disease is characterized by the three syndromes:
- Peracute fatal diarrhea
- Moderate diarrhea of 3-4 days' duration, accompanied by fecal shedding of the inoculated organism and reduced body weight gain
- Fecal shedding of the organism with reduced weight gain but without diarrhea.

The role of the rotavirus in the pathogenesis of postweaning diarrhea is uncertain. The rotavirus can be found in the feces of healthy unweaned and weaned pigs. The virus is capable of infecting and destroying villous epithelial cells which could contribute to the partial villous atrophy, loss of digestive enzyme activity, malabsorption and reduced growth rate. Experimental inoculation of an enteropathogenic E. coli and the rotavirus causes a more severe disease than either agent does alone. The effects of experimentally induced villus atrophy in weaned pigs infected with the transmissible gastroenteritis virus and a K88 enterotoxigenic E. coli have been examined.

Changes in the mucosa of the small intestine of recently weaned pigs have been observed and are the subject of much controversy. There is a reduction in the length of the villi, a marked reduction in intestinal disaccharidase activity and an increase in the depth and activity of the intestinal crypts. These changes are maximal at 3-7 days following weaning, persisting until the second week and coinciding with the reduced growth rate.

**CLINICAL FINDINGS**

The postweaning reduction in growth rate may affect 50-100% of the pigs within a few days after weaning and persist for up to 2 weeks. In some situations diarrhea may not develop in any of the pigs in the group. A reduction in feed intake, gaunt abdomens, and lusterless hair coats are characteristic findings of piglets with postweaning 'check'. They may appear unthrift for 10 days to 2 weeks, by which time they will improve remarkably.

Most commonly one or two pigs, in good nutritional condition, are found dead with little having been seen in the way of premonitory signs. At this time the others within the group may appear normal but closer examination will reveal several pigs showing mild depression and moderate pyrexia. A postmortem examination of dead pigs should be conducted early in the examination. A proportion of the group will develop diarrhea within 6-24 hours and by 3 days after the initial onset the morbidity may approach 100%. Feed consumption falls precipitously at the early stages of the outbreak but affected pigs will still drink. Affected pigs may show a pink discolouration of the skin of the ears, ventral neck, and belly in the terminal stages. Diarrhea is the cardinal sign – the feces are very watery and yellow in color but may be passed without staining of the buttocks and tail. Pyrexia is not a feature in individual pigs once diarrhea is evident. Affected pigs show a dramatic loss of condition and luster and become progressively dehydrated. Voice changes and staggering, incoordinated movements may be observed in the terminal stage in some pigs. The course of an outbreak within a group is generally 7-10 days and the majority of pigs that die do so within the initial 5 days. Surviving pigs show poor growth rate for a further 2-3 weeks and some individuals show permanent retardation in growth. In outbreaks in early weaned pigs diarrhea is usually evident before death occurs. There is some evidence to show that the postweaning diarrhea may be activated by porcine reproductive and respiratory syndrome.

**CLINICAL PATHOLOGY**

Culture of the feces and intestinal contents for enterotoxigenic strains of E. coli is indicated.

**NECROPSY FINDINGS**

Pigs dying early in the course of the outbreak are in good nutritional condition but those dying later show weight loss and dehydration. Mild skin discolouration of the ears and ventral areas of the head, neck, and abdomen is usually present. In acute cases there is a moderate increase in...
peritoneal fluid and barely perceptible fibrinous tags between loops of the small intestine may be present. The vessels of the mesentery are congested and occasionally petechial hemorrhages and edema are present. The gastric mucosa is congested and an infarct is usually present along the greater curvature. The small intestines are dilated and contain yellow mucoid liquid or occasionally blood-stained material. The mucosa of the small intestine is congested and sometimes there are hemorrhagic areas. The content of the large intestine is fluid to fibrinous tags between loops of the small intestine is congested and some adherence to intestinal villi. Other changes are those commonly associated with endotoxemia, especially microvascular thrombosis.

Microscopically, there is usually bacterial adherence to intestinal villi. Other changes are those commonly associated with endotoxemia, especially microvascular thrombosis in a variety of organs.

**Samples for confirmation of diagnosis**
- Bacteriology – mesenteric lymph node, segment of ileum, colon (CULT)
- Histology – formalin-fixed stomach, several segments of small intestine, colon, liver, lung, spleen (LM).

**DIFFERENTIAL DIAGNOSIS**

Postweaning diarrhea is the prime consideration in pigs that are scouring or dying within a 3–10-day period of some feed or management change. Swine dysentery and salmonellosis are manifested by diarrhea and death but they are not necessarily related to weaning or feed change, and both are more common in older growing pigs. Salmonellosis poses the greatest difficulty in initial diagnosis from coliform gastroenteritis. In salmonellosis, the feaces are generally more fetid with more mucus, mucosal shreds, and occasionally blood, and the skin discoloration is more dramatic. On necropsy examination enlarged hemorrhagic peripheral and abdominal lymph nodes and an enlarged pterygopalatine ganglion are more suggestive of salmonellosis; however, cultural differentiation is frequently required. If there is doubt the pigs should be treated to cover both conditions until a final decision is obtained. The onset of swine dysentery is comparatively more insidious than that of postweaning diarrhea, the characteristic feaces, clinical and epidemiological pattern and postmortem lesions differentiate these two conditions.

**TREATMENT**

A Swedish study showed that, except for resistance to tetracyclines, sulfaethoxazole, and streptomycin, antibiotic resistance is not unduly spread across E. coli isolates. A Spanish study was similar. Tetracyclines should not be the first choice of treatment because of the rapid acquisition of resistance. Nearly all isolates are highly susceptible to enrofloxacin, gentamicin, and neomycin.

It is imperative that treatment of all pigs within the group be instigated at the initial signs of the onset of postweaning diarrhea, even though at that time the majority of pigs may appear clinically normal. Delay will result in high mortality rates. Any pig within the group that shows fever, depression, or diarrhea should be initially treated individually both parenterally and orally and the group should then be placed on oral antibacterial medication. Water medication is preferable to medication through the feed as it is easier to institute and affected pigs will generally drink even if they do not eat. Neomycin, tetracyclines, sulfonamides, or trimethoprim-potentiated sulfonamides and ampicillin are the usual drugs of choice. Danofloxacin is safe and effective. **CONTROL**

Recommendations for effective and economical control of postweaning reduced growth rate and postweaning diarrhea in pigs weaned at 3 weeks of age are difficult because the etiology and pathogenesis of this complex disease are not well understood. Epidemiologically, the disease is associated with weaning and the effects of the syndrome consumed before and after weaning. In all cases the piglet should be 4.5 kg (10 lb) and preferably 5.5 kg (12 lb) at weaning.

A wide variety of techniques, including intestinal acidification, antimicrobial medication in water or feed, environmental modifications, competitive exclusion, feeding probiotics, binding agents such as eggs, milk, or bacterial byproducts (most of these studies show they do not work), zinc oxide, or vaccination of sows and piglets with toxoids have been tried. The use of dietary egg yolk antibodies also does not appear to be effective. Intestinal acidification reduces the binding of the E. coli to the epithelial surface and a pH of 3.5–4.0 at the trough or nipple drinker is best. Citric acid, formic acid, propionic acid, or a citric acid–copper sulfate mixture can be used. Zinc oxide in particular stabilizes the intestinal flora. Piglets given lactose and fiber were least affected and the next least affected were animals that received zinc oxide. Pigs fed dietary antibiotic growth promoters and zinc oxide had lower counts of anaerobic bacteria in their feces than control piglets. The removal of these ingredients from the diet will increase days to slaughter.

It has been traditionally accepted, without reliable evidence, that the sudden transition in diet at weaning is the major predisposing factor. However, as presented under Epidemiology, the experimental observations are conflicting. One set of observations indicates that, if pigs eat a small quantity of creep feed before weaning, they are then ‘primed’ and develop an intestinal hypersensitivity that, following the ingestion of the same diet after weaning, results in disease. It has been suggested that piglets should consume at least 600 g of creep feed before weaning in order to develop a mature digestive system. Another set of observations indicates that those pigs that consumed an excessive quantity of feed after weaning developed the disease. The complete withholding of creep feed followed by abrupt weaning at 3 weeks of age seemed to have a protective effect, possibly associated with a low dietary intake. Farms with lower rates of postweaning diarrhea used their first piglet ration (phase 1 feeding) for much longer and also changed over to the second ration over a much longer period. Competitive exclusion has been shown to be of benefit.

Competitive exclusion has been shown to be of benefit.
The recommendations set out here are based on the hypothesis that the consumption of adequate quantities of creep feed prior to weaning is the most effective and economical practice. Every effort should be made to minimize the stress associated with weaning. Stressors influence the fecal shedding of enterotoxigenic *E. coli* by young piglets by a mechanism that may not involve modulation of the immune response. In order to avoid a sudden transition in diet at weaning, creep feed should be introduced to the suckling piglets by at least 10 days of age. It is important that the creep feed and feeder area be kept fresh to maintain palatability. The same feed should be fed for at least 2 weeks following weaning and all subsequent feed changes should be made gradually over a 3-5 day period. Feed restriction in the immediate 2-week period following weaning may reduce the incidence but generally is not successful. It is a common field observation that the incidence of diarrhea varies with different sources of feed but experimental studies confirm this relationship are not available.

Where possible, at weaning the sow should be removed and the pigs should be kept as single litters in the same pen for the immediate postweaning period. If grouping of litters is practiced at this time, or later, the pigs should be grouped in equivalent sizes. Multiple suckling in the postweaning period may reduce stress associated with grouping of part-weaned pigs. With all pigs, but especially those weaned earlier than 6 weeks, the pen construction should be such as to encourage proper eliminative patterns by the pigs and good pen hygiene (see Salmonellosis) so as to minimize oral–focal cycling of hemolytic *E. coli*. The environment also appears especially important in this group and draft–free pen construction should be such as to encourage proper ventilation. It is preferable to wean pigs on weight rather than age and in many piggeries a weaning weight of less than 6 kg is associated with a high incidence of postweaning enteric disease.

The inclusion of an antimicrobial in the feed or water to cover the critical period of susceptibility (generally for 7–10 days after weaning) can be used as a preventive measure. Apramycin at the rate of 150 g/tonne of feed for 2 weeks after weaning may be associated with improved growth rates and a reduction in mortality. The high incidence of drug resistance in isolates of *E. coli* makes prior sensitivity testing mandatory and the antibiotic may need to be changed if new strains gain access to the herd. The routine use of prophylactic antibiotics for this purpose needs to be considered in relation to the problem of genetically transmitted drug resistance, however it is currently often necessary for short-term control of a problem.

Vaccination may offer an alternative method of control. However, currently there are no vaccines available for the control of colibacillosis in weaned pigs. Oral inoculation with 5 × 10^8–10^9 non-toxigenic strains can be followed with K88 at day 1 of move, K88/F18ab at day 7 and F18 at days 13–15. Only the oral vaccines with the preformed fimbriae appear to produce any protection to homologous fimbrial variant. The results vary and some authors think that the prolonged transit time in the stomach after weaning may deactivate the F4 fimbriae when this has been used as a fimbrial vaccine. Microencapsulated enterotoxigenic *E. coli* and detached fimbriae have been used for peroral vaccination in pigs. Parenteral vaccination for the control of coliform gastroenteritis has proved of variable value, probably because parenterally administered antigens do not usually stimulate the production of IgA antibodies and intestinal immunity. Oral immunization by the incorporation of *E. coli* antigens into creep feed has been shown to reduce the incidence and severity of postweaning diarrhea. A live avirulent *E. coli* vaccine for K88*, LT* enterotoxigenic colibacillosis in weaned pigs provided protection experimentally. Rearing early-weaned piglets artificially for the purpose of increasing the efficiency of the sow is an attractive management concept. However, high death losses from diarrhea have slowed progress in this new development. The incorporation of antibiotics in the diet of such piglets as a prophylactic measure should be possible and is being explored.

The ultimate control is by removing the receptor gene in the population and although this has been done experimentally these animals are not yet available in large numbers commercially.

### CEREBROSPINAL ANGIOPATHY

Cerebrospinal angiopathy is a sporadic disease of recently weaned pigs manifested primarily by neurological signs. In some areas the disease is the more common cause of central nervous system disorders in this age group of pigs. The disease affects only one or a few pigs within a litter of a group occurring up to 5 weeks after weaning although a similar condition has been reported in fattening and adult pigs. The disease is characterized by the variety of neurological signs that it presents. Incoordination and a decreased central awareness are common presenting signs but abnormal head position, aimless wandering and persistent circling may also be observed.
There is usually apparent impairment of vision. Fever is not a feature and the clinical course may last for several days. Affected animals may die but more commonly are destroyed because of their emaciated condition. Wasting without neurological disorder may also occur. They are also prone to savaging by unaffected penmates. Histologically the disease is characterized by an angiopathy that is not restricted to the central nervous system. The similarity of the angiopathy to that seen in chronic edema disease has led to postulation that this disease is a sequel to subclinical edema disease. The disease has been reported occurring in pigs 15–27 days after experimental E. coli infection. The characteristic feature is the presence of perivascular eosinophilic droplets.

The main differential diagnosis is that of spinal or brain abscess and the porcine viral encephalomyelitides. Affected pigs should be housed separately as soon as possible. The characteristic feature is the presence of perivascular eosinophilic droplets.

S. enterica, the type species, and S. bongori. S. enterica subsp. enterica is divided into six subtypes. S. enterica subsp. enterica I is divided into serotypes enteritidis, typhimurium, typhi, and choleraesuis. At the first citation of a serotype the genus name is given followed by the word ‘serotype’ or the abbreviation ‘ser.’ and then the serotype name (e.g. Salmonella serotype or ser. typhimurium). Subsequently, the name may be written with the genus followed directly by the serotype name (e.g. Salmonella typhimurium or S. typhimurium). The majority (59%) of the 2463 Salmonella serotypes belong to S. enterica subsp. I (S. enterica subsp. enterica).

Serovars of S. enterica subsp. I are associated mainly with warm-blooded vertebrates and are responsible for most Salmonella infections in humans and domesticated animals. Salmonella serovars differ in the range of hosts they can infect and in the nature of disease that may result: this difference is referred to as serovar-host specificity. Some Salmonella serovars, for example typhimurium and enteritidis, can infect a relatively wide range of hosts and are termed ubiquitous. They are usually associated with a relatively mild enteric disease, although in some hosts, such as mice, the disease can be systemic and severe. Other serovars are very restricted in their host range, causing severe systemic disease in only one host. For example, S. typhi is restricted to infection in humans, Salmonella abortusovis to infections in sheep, Salmonella dublin in cattle, Salmonella abortusequi in horses, and Salmonella choleraesuis in pigs.

A third group of serovars is associated predominantly with one species but may also infect a limited number of other hosts. For example, S. dublin is usually associated with cattle but natural infection by this serovar may also occur in other animals, including humans and sheep. The nature of disease associated with this third group of serovars is variable, depending on the specific combination of serovar and host, although

EPIETIOLOGY

The genus Salmonella belongs to the family Enterobacteriaceae. Currently there are 2463 serotypes (serovars) of Salmonella. The antigenic formulae of Salmonella serotypes are defined and maintained by the World Health Organization (WHO) Collaborating Centre for Reference and Research on Salmonella at the Pasteur Institute, Paris, France, and new serotypes are listed in annual updates of the Kauffman–White scheme.

In 1986, the Subcommittee of Enterobacteriaceae of the International Committee on Systematic Bacteriology recommended that the type species for Salmonella be changed to Salmonella enterica. However, Salmonella typhi and Salmonella choleraesuis were maintained as type species. The literature on Salmonella nomenclature has been reviewed. According to the current system used by the Centers for Disease Control, the genus Salmonella contains two species, each of which contains multiple serotypes.

The two species are S. enterica, the type species, and S. bongori. S. enterica subsp. enterica is divided into six subtypes. S. enterica subsp. enterica I is divided into serotypes enteritidis, typhimurium, typhi, and choleraesuis. At the first citation of a serotype the genus name is given followed by the word ‘serotype’ or the abbreviation ‘ser.’ and then the serotype name (e.g. Salmonella serotype or ser. typhimurium). Subsequently, the name may be written with the genus followed directly by the serotype name (e.g. Salmonella typhimurium or S. typhimurium). The majority (59%) of the 2463 Salmonella serotypes belong to S. enterica subsp. I (S. enterica subsp. enterica).

Serovars of S. enterica subsp. I are associated mainly with warm-blooded vertebrates and are responsible for most Salmonella infections in humans and domesticated animals. Salmonella serovars differ in the range of hosts they can infect and in the nature of disease that may result: this difference is referred to as serovar-host specificity. Some Salmonella serovars, for example typhimurium and enteritidis, can infect a relatively wide range of hosts and are termed ubiquitous. They are usually associated with a relatively mild enteric disease, although in some hosts, such as mice, the disease can be systemic and severe. Other serovars are very restricted in their host range, causing severe systemic disease in only one host. For example, S. typhi is restricted to infection in humans, Salmonella abortusovis to infections in sheep, Salmonella dublin in cattle, Salmonella abortusequi in horses, and Salmonella choleraesuis in pigs.

A third group of serovars is associated predominantly with one species but may also infect a limited number of other hosts. For example, S. dublin is usually associated with cattle but natural infection by this serovar may also occur in other animals, including humans and sheep. The nature of disease associated with this third group of serovars is variable, depending on the specific combination of serovar and host, although

in the predominant serovar–host combination the disease is usually systemic.
The serotypes (serovars) that most commonly cause salmonellosis in farm animal species are as follows:

- **Cattle:** S. typhimurium, S. dublin, Salmonella newport
- **Sheep and goats:** S. abortusovis, S. typhimurium, S. dublin, Salmonella anatum
- **Pigs:** S. typhimurium, S. choleraesuis
- **Horses:** S. typhimurium, S. abortusequi, S. anatum, S. newport, S. enteritidis, Salmonella heidelberg, Salmonella arizona, Salmonella angora.

The molecular methods are now available for epidemiological investigation of *S. enterica* subsp. *enterica* infections.  

**EPIDEMIOLOGY**

The epidemiology of salmonellosis is complex, which often makes control of the disease difficult. The epidemiological patterns of prevalence of infection and incidence of disease differ greatly between geographical areas depending on climate, population density, land use, farming practices, food processing and processing technologies, and consumer habits. In addition, the biology of the serovars differs so widely that considerations of salmonellosis, *Salmonella* infections or *Salmonella* contamination are inevitably complex.

**Prevalence of infection**

Surveys from various countries indicate a 13–15% infection rate in dairy cows in New Zealand, with similar rates in calves and sheep, and 4% in beef cattle. In the Netherlands, the infection rate is 25% in healthy pigs at abattoirs but similar investigations elsewhere record 10% (New Zealand) and 6% (UK). American figures indicate a 10–13% infection rate. 

Salmonellas were isolated from the mesenteric lymph nodes and oveal contents of 84% of slaughtered sows in a Minnesota abattoir. These data are based on abattoir material and should be viewed with caution because of the very rapid increase in infection rate which occurs when animals are held over in yards for several days.

A national survey of the prevalence of fecal carriage of *Salmonella* in healthy pigs, cattle, and sheep at slaughter, and of pig carcass contamination with *Salmonella* in Great Britain found the carriage rate in prime slaughter cattle and sheep was very low compared with pigs. In pigs, the fecal carriage rate was 23.0%, although carcasses were only moderately contaminated at 5.3%. The meat juice ELISA results indicated that 152% of tissue fluid samples were positive at the 40% cutoff level and 35.7% at the 10% experimental cutoff level. This indicates that pigs are exposed to a relatively high level of *Salmonella* during the weeks prior to slaughter. The carriage rate in cattle and sheep was very low, ranging from 0.1–1.7%.

In the UK, *S. dublin* and *S. typhimurium* account for nearly 90% of bovine salmonellosis. *S. typhimurium* is endemic in calves, especially those purchased at livestock markets and raised for beef or veal. In the USA, the organism is shed by calves on 16% of farms sampled; in Ontario, calves on 22% of farms surveyed were found to shed *Salmonella* spp. In a survey of 47 dairy farms in Ohio, of 452 calves sampled, 10 calves from seven farms were culture-positive. *Salmonella* serotypes isolated were *S. dublin*, *S. typhimurium*, *S. enteritidis*, *S. agona*, *Salmonella vibankakasa*, and *Salmonella montevideo*. Bulk milk tank filters from these dairies were also submitted for culture; *Salmonella* spp. were isolated from one of 50 filters and two calves from this herd were found to be shedding *Salmonella* spp. of the same serotype.

The geographical distribution of the serotypes differs: *S. typhimurium* has a universal distribution; *S. dublin* has a more patchy habitat. In the USA, up until 1948, it was limited to California and as recently as 1971 it had not been reported in cattle east of the Rocky Mountains. In 1980, the first case of *S. dublin* occurred in Indiana. The movement of infected adult cattle and calves is responsible for the introduction of infection to areas where it had not previously been diagnosed. In a California survey of 60 dairy herds, milk samples and serum samples tested with an ELISA for antibodies against *Salmonella* serogroup B, C1, and D1 antigens found that 75% of dairy herds surveyed had cows with serological evidence of recent exposure to salmonellas, especially *S. typhimurium* and *S. enteritidis*. The prevalence of fecal shedding of *Salmonella* by dairy cattle marketed in Washington state is estimated to be 4.6 per 1000 head. Neonatal calves under 28 days of age may be shedding *Salmonella* without any evidence or recent herd history of clinical disease. Australia has had little *S. dublin* but there has been a marked increase in outbreaks of abortions, gastroenteritis and calf deaths due to *S. dublin* infection in Queensland dairy cattle since 1983. South Africa, South America, the UK, and Europe have had *S. dublin* as the principal pathogen for cattle for some time. It has also come to surpass *S. abortusovis* as a cause of abortion in sheep.

In Danish pig herds, *Salmonella* infections are usually subclinical. A survey in 1993–94 found that 22% of 1368 larger herds were infected with *Salmonella*. The most prevalent serotypes were *S. typhimurium* (62% of infected herds), *Salmonella infantis* (10%), *Salmonella* 4,12b (8%), and *Salmonella* panama (5%). Phage typing of isolates of *S. typhimurium* from pigs and humans reveals that pigs are probably a major source of the infection in humans in Denmark.

In Sweden the prevalence of salmonellosis in food-producing animals is low because of the *Salmonella* control programs, which started in 1961 with the aim of keeping meat-producing animals free from *Salmonella* in Sweden. When Sweden joined the European Union in 1995, surveillance of *Salmonella* in cattle, pigs, and poultry at slaughter included in the control programs. Any finding of *Salmonella* from animals or in feeds or feed production, regardless of serotype, is notifiable to the Swedish Board of Agriculture. The occurrence of *Salmonella* in animals and in the feed production in Sweden remained relatively stable from 1993–97.

The incidence of salmonellosis in animals and humans may change within a geographical area over a period of years. In Scotland, the incidence of *S. typhimurium* DT104 in cattle peaked in 1996 and then decreased annually to 2001. Similar declines have been observed in its incidence in sheep and pigs. In humans, the number of reports of *S. enteritidis* PT4 peaked in 1997 and then declined to a low level by 2001.

*Salmonella* *infantis* and *S. typhimurium* persist among cattle in Finland, with a low prevalence rate of 2% of farms, but these serovars play a major role in human salmonellosis. Molecular epidemiology is now used to determine if strains isolated from cattle are the same as those affecting humans. Multiple genetic typing of *S. typhimurium* isolates of different phage types (DT104, U302, DT204B, and DT 49) from animals and humans in England, Wales, and Northern Ireland identified different degrees of polymorphism. A prevalent genomic clone, as well as a variety of less frequent clones, is present for each of the phage types. Molecular epidemiology of *S. typhimurium* isolates from wild-living birds, domestic animals and the environment was investigated in Norway using pulse-field gel electrophoresis. Passerines (perching birds) constitute an important source of infection for humans in Norway, whereas gulls and pigeons represent only a minor source of human *S. typhimurium* infections. Passerines, gulls, and pigeons may constitute a source of infection of domestic animals and feed plants. Some isolates from cattle were confirmed as *S. typhimurium* DT104 for the first time.
phage types were found in humans and murium. In general, similar sero- and phage types were found in humans and animals, although distinct types were more common in animals.

Monitoring of the population and herd Salmonella seroprevalence in pigs and sows provided a baseline for the success of future intervention and control strategies for Salmonella in pork. The seroprevalence of Salmonella in sows and finishing pigs in the Netherlands was determined using indirect ELISA on blood samples collected at the abattoirs. The population prevalence for finishing pigs in 1996 and 1999 was 23.7% and 24.5%, respectively, and for sows 40.5% and 60.4%, respectively. The prevalence of nosocomial salmonellosis is an important problem for horses in veterinary hospitals. It is also possible that many of the unidentified enteritides of horses may have been associated with Salmonella spp.

Pigs

In the midwestern USA, salmonellosis associated with the host-adapted facultative intracellular S. choleragenes is an important cause of economic loss in pig herds because of death and reduced productivity. It is the most frequent serotype recovered from pigs and is isolated from more than 95% of porcine salmonellosis outbreaks in Iowa. The incidence has been increasing in some geographical areas. S. typhimurium causes enterocolitis in young pigs.

Sheep

Salmonellosis is commonly encountered when sheep are assembled at high stocking rates. It was one of the main contributing causes of death in sheep exported by sea from Australia to the Middle East, although inanition is usually the primary cause.

In the 1990s there was an increase in the incidence of salmonellosis in sheep associated with S. enterica serotype Derby, agona, typhimurium, brandenburg, mbendaka, and heidelberg. The majority of Salmonella infections are subclinical, associated with a large number of serotypes. A national US survey for fecal Salmonella shedding by pigs most frequently found S. enterica serotypes Derby, agona, typhimurium, brandenburg, mbendaka, and heidelberg. The prevalence of Salmonella in Danish pork decreased from 3.5% in 1993 to 0.7% in 2000 following introduction of a national program to reduce the prevalence of salmonellas in pork.

Occurrence

Salmonellosis occurs universally in all species.

Cattle

The disease has assumed major importance because of outbreaks in dairy cattle and the occurrence of infections in humans. Of major concern is the increased incidence of outbreaks of salmonellosis in dairy cattle and humans associated with S. typhimurium definitive type (DT104) in the USA and the UK. This strain is multiple-antibiotic-resistant and is classified as R-type ACSSuT by being resistant to ampicillin, chloramphenicol, streptomycin, sulfonamides, and tetracycline. The strain is now the second most prevalent Salmonella serotype in humans in England and Wales and the most common Salmonella serotype isolated from cattle. A case-control study identified the following risk factors associated with infection with the multiple-resistant S. typhimurium DT104:

- A high population density of feral cats around the farm
- Evidence of wild bird access to feed supplies
- Purchase of animals from dealers.

A high frequency of antibiotic-resistant phage types of S. typhimurium has been reported from Australia. The intensification of cattle production and management has played a large part, but the emergence of S. dublin as a common pathogen has been most important. In recent years there has also been a large increase in notifications of exotic species of Salmonella such as S. agona and S. newport, which have mostly originated from the use of unusual food materials of animal and fish origin.

In a review of 40 cases of clinical salmonellosis in horses that were diagnosed in one clinic, the case-fatality rate was 60%. Epidemics of salmonellosis affecting up to 40% of foals under 8 days of age on one Thoroughbred horse farm have been reported.

Methods of transmission

Salmonellas are spread by direct or indirect means. Infected animals are the source of the organisms; they excrete them and infect other animals, directly or indirectly by contamination of the environment, primarily feed and water supplies. The farm animal may be infected in different ways: by animal-to-animal transmission, especially of host-adapted serovars, by contaminated animal feed, and by a contaminated environment (soil, birds, rodents, insects, water supplies). Liquid wastes from infected animals may contaminate the environment directly, including streams, rivers, and pastures. Bacteria may also be disseminated during the transport of infected animals and during the holding of animals in a lairage prior to slaughter. In both situations, the excretion of salmonellosis is exacerbated by the stress imposed.

In the UK, surplus calves from dairy farms are sold at public market and moved to rearing farms. The mixing of young susceptible calves and their subsequent transportation is an efficient mechanism for the rapid dissemination of Salmonella. The dealers’ premises can serve as reservoirs of infection despite cleaning and disinfection. Many vehicles and markets are contaminated with Salmonella, and S. typhimurium DT204C, the most common Salmonella isolated from calves, is the most frequent isolation.

The introduction of infected carrier animals into a herd is a common cause of outbreaks of clinical salmonellosis in dairy herds that are expanding in size.

The organism can persist for an average of 14 months in the environment where calves are reared. Salmonella does not survive for more than 5 days in bovine urine not mixed with feces but will survive in dried bovine feces for up to 6 years. After a clinical outbreak of salmonellosis, for example in a dairy herd raising its own replacements, the premises cannot be declared to be Salmonella-free solely on the basis of freedom from clinical cases over the next few years or on the basis of comparatively high herd performance. In large dairy herds with modern free-stalls that recycle water in their manure flush systems, it may be possible to isolate Salmonella serovars for several years following an outbreak of clinical salmonellosis.

The organisms may be found in recycled water samples, bulk tank milk filters, and in sewage from farms with cattle. Salmonella can also be carried in the manure of dairy cows. Salmonella can be transmitted to humans by consumption of contaminated food or water, by exposure to infected animals, and by contact with contaminated environment. Studies have shown that S. enterica serovar dublin, a human pathogen, can survive and multiply in feral cats, raising concern for the potential for human infection. Salmonella can also be transmitted to humans by consumption of contaminated food or water, by exposure to infected animals, and by contact with contaminated environment. Studies have shown that S. enterica serovar dublin, a human pathogen, can survive and multiply in feral cats, raising concern for the potential for human infection.
filters and the feces of calves and adult cows.

Salmonellas can be isolated from piggery waste water after orthodox pondage treatment, and the reinculcation of contaminated water through the piggery serves as a constant source of the organism. Housing of finishing-age pigs in barns with open-flush gutters may contribute to increased shedding of Salmonella compared to pigs housed on partially slotted floors. Methanogenic fermentation in waste ponds does not eliminate Salmonella from piggery waste; acidogenic fermentation with the production of free acid can destroy salmonellas and other potential pathogens.

During slaughter, fecal contamination of the carcass commonly occurs and can be carried through all slaughter procedures up to the processing of the raw products. Milk can be contaminated directly by cows that excrete the organism in the udder, especially those cattle infected with S. dublin and Salmonella newaster, both of which have adapted to colonize the bovine mammary gland. Although S. typhimurium is not usually excreted in the milk, except during the febrile stage of clinical disease, it has been reported to have been persistently isolated from the milk of a healthy cow. S. enteritis has been isolated from ill humans, milking filters, milk from a bulk tank and milk from one quarter of a 5-year-old dairy cow that persistently shed the organism in the milk for several months. Milk is most likely to become contaminated by feces, either from an animal with clinical salmonellosis or from a healthy carrier animal, during the milking process. Additional sources of contamination during milking are use of polluted water or contaminated equipment. Workers who lack personal hygiene skills and have clinical salmonellosis or are chronic shedders of the organism may also contaminate milk supplies.

Airborne transmission can be a primary mode of infection of S. typhimurium. Studies have shown that the organism can survive in air sufficiently long to present a significant hazard of air-borne spread.

The carrier state

Because salmonellas are facultative intracellular organisms that survive in the phagolysosome of macrophages, they can evade the bactericidal effects of antibody and complement. Thus, persistence of infection in animals and in the environment is an important epidemiological feature of salmonellosis. When an animal is infected with S. dublin it may become a clinical case or an active carrier, shedding organisms constantly or intermittently in the feces. It may also become a latent carrier with infection persisting in lymph nodes or tonsils but no salmonellas in the feces, or even a passive carrier which is constantly acquiring infection from pasture or the calf-pen floor. But invasion of tissues may not occur and when the animal is removed from the environment the infection disappears. However, these animals probably multiply the salmonellas without becoming permanent carriers. The importance of the latent carriers is that they can become active carriers or even clinical cases under stress, especially at calving time. The cattle themselves then become the means by which the infection is retained in the herd for long periods. A major problem with the control of S. dublin infection is that the outbreak of the organism, unlike persistent excreters, cannot be readily identified by fecal culture or serological methods. In a 3-year study of one dairy herd, the organism was isolated occasionally from the feces of adult cattle, from some cattle after parturition, and from some calves within 24 hours after birth. In some dairy herds, the organism may persist for many years with a low incidence rate of clinical disease.

For S. typhimurium the donor can be any domestic animal species, including humans, or any wild animal or bird. Although all infected adults become carriers it is rarely for any length of time, and calves rarely become carriers. In sheep and cattle the carrier state may persist for as long as 10 weeks, and in horses up to 14 months.

Experimental infection of pigs at 7–8 weeks of age with a single oral dose of S. typhimurium can persist continually, at least until market age. Regardless of the route of infection, S. choleraesuis can persist in the tonsil and ileocolic lymph nodes, ileocolic junction and colon, and can be excreted in the feces of experimentally infected pigs for at least 12 weeks. The amount of shedding and persistence of infection is dose dependent. Low doses of S. choleraesuis can be easily cleared, moderate doses can persist for at least 2 months, and high doses result in long-term carrier states. After intranasal inoculation of S. typhimurium, the organism rapidly appears in the intestines, suggesting that the tonsils and lungs may be important sites for invasion and dissemination of Salmonella species. Experimental infection with a zootocic strain of S. newport can also be established in pigs at 7 weeks of age to persist until market age. Long-term persistence of infection is limited generally to the palatine tonsils, the intestinal tract caudal to the mid-jejunum and their lymph nodes. The prevalence of the organism in pigs creates a reservoir of infection for animals and humans. The transmission of salmonellosis in pigs can occur in a few days. Exposure to relatively low levels of S. choleraesuis may result in high morbidity and initiate a severe outbreak in naive pigs within several days of being exposed to infected pigs. Only a small fraction of carrier pigs are responsible for the maintenance of the pathogen in a pig population.

Risk factors predisposing to clinical disease

The clinical characteristics of salmonellosis in large animals vary depending on the various management systems used, the intensity of stocking, whether or not the animals are housed, and the epidemiological characteristics of the different Salmonella species. Thus, salmonellosis in cattle is a very serious and persistent disease in areas where it is caused principally by S. dublin. But where it is associated with S. typhimurium the disease is sporadic and, even though it is highly fatal to individual animals, it is not a serious disease. Although there are probably similar differences with other species, they are not particularly well defined. The difference between the diseases associated with S. dublin and S. typhimurium is the marked tendency for S. dublin to persist in adult cattle and create a significant reservoir of carrier animals. S. typhimurium does not do so as much, so that the disease is likely to subside after an initial exposure and to recur only when the source of infection, from rodents or feedstuffs, or sewage or slurry, reappears. This does not of course preclude the disease from persisting in a flock or herd for long periods. S. typhimurium infection persisted in a large dairy herd for 3.5 years. While the incidence rate of clinical disease declined over the study period, the organism could still be cultured from the bulk tank milk filters, which may have been associated with one cow identified as a milk excretor. Three associated human disease incidents occurred following the consumption of raw milk.
antimicrobials or anthelmintics, acute deprivation of food, or parturition is usually necessary to cause the disease salmonellosis, as distinct from infection with Salmonella sp.

The portal of infection in salmonellosis is almost always the mouth, so that the severity of the disease in an individual, or of an outbreak in a group, depends on the degree of contamination and the environmental conditions of temperature and dryness that determine the survival time of the salmonellas. Just as important is the influence of the host on the outcome of the infection. Many animals become infected naturally and are passive carriers; they shed salmonellas in their feces without clinical disease but only for the duration of their cohabitation with other infected animals. It is also possible to reproduce salmonellosis experimentally in most animals using a sufficiently large dose of a virulent strain of the organism. There still remains the common occurrence of the animal that is a subclinical carrier of the infection but develops clinical salmonellosis when exposed to stressors such as long transportation, hospitalization, severe feed deprivation or parturition.

Genetic resistance to salmonellosis in domestic animals

There is evidence of a strong genetic association with resistance to salmonellosis in several economically important domestic animal species. However, as yet, selective breeding for resistance traits is not utilized in control of diseases or the carriage of Salmonella in any of these species. The value of a particular resistance trait in reduction of disease must be balanced against other factors such as productivity of meat and milk. The control of Salmonella colonization of the gastrointestinal tract of food animals, particularly where intensive rearing occurs, as in pig units, would appear to be a particularly useful objective with enormous potential public health benefits. There may be a role for several inherited immunological traits, including polymorphonuclear leucocyte function and lecithin-induced mitogenic proliferation.

The interrelationships between the risk factors of the host, the environment, and the pathogen are described here according to species differences.

Dairy cattle

In calves, the disease is usually endemic on a particular farm, although outbreaks can occur. In adult cattle at pasture the disease is less common. This is particularly so with S. typhimurium infections, but S. dublin affects both young and adult cattle. Spread between calves in communal pens is by fecal–oral contamination.

Infection of the newborn calf may be from the dam because many cows that are latent shedders become active shedders at parturition. The calves are not infected at birth but become infected from the environment. In adult cattle, S. dublin is the common infection and occurs sporadically, but as outbreaks when stressed occur. Spread is usually by the oral route and in cattle at pasture is greatly enhanced by persistently wet conditions. Wild mice are potential reservoirs of S. dublin in dairy herds.

Risk factors identified in dairy and beef cattle herds with clinical salmonellosis in Virginia included herd size, exposure to wild geese, rodent activity in housing and feed areas and spreading manure on bordering property. Previous antimicrobial treatment of cattle with laboratory-confirmed Salmonella infections increases the probability of isolating salmonellas.

In cattle, deprivation of feed and water is a common risk factor, usually as a result of transportation, but recent calving, sudden changes in the composition of the diet, vaccination with a living vaccine that produces a systemic reaction, treatment with irritant compounds such as carbon tetrachloride for fluke, and fluke infection can precipitate clinical disease. However, prior infection of calves can provide resistance to experimental infection. In some herds there are sporadic cases in cows as they calve, usually within 1 week afterwards. In grazing cattle there is a distinct seasonal incidence in late summer, fall, and early winter, probably because of greater exposure to infection at pasture.

The pH of rumen contents has been shown to affect the number of salmonellas surviving passage through the rumen. A high volatile fatty acid content and a low pH, such as prevails when a ruminant is on full feed, is unfavorable to salmonellas passing through the forestomachs.

The epidemiological and biological characteristics of three dairy herds in California have been examined and several risk factors were identified that varied between dairies. The various sources of salmonellas in dairy farms indicate that they are part of a larger ecosystem. The prevalence of fecal shedding indicated the magnitude of environmental contamination possible. Animals were exposed to many Salmonella serotypes via feed contaminated through irrigation of crops with effluent or dairy wastes. Salmonella contamination of irrigation water by human sewage was identified as a potential source of exposure with S. agona, S. montevideo, and Salmonella manila.

Nutritional stress caused by transition diets and heat stress was associated with outbreaks in some herds. Salmonellas were isolated from aseptically collected composite milk samples, and from bulk-tank and inline milk filters. Such contamination can result in contamination of human dairy products. A large number of Salmonella serotypes were present in cull dairy cows at slaughter with S. montevideo being most common. The overall prevalence of Salmonella spp. in cull dairy cows at slaughter across the USA was 23.1%, with a range accounting for location and season between 43.7% and 54.5%. This could burden the Hazard Analysis Critical Points Programs implemented in abattoirs. Procedures to reduce Salmonella infection at the farm and during transport to slaughter could reduce the risk of spread during the slaughter process.

The water supplies of dairy calves in California dairy herds may be contaminated with S. typhimurium. Water offered to weaned dairy calves in a continuous water-tank-filling method was a risk factor compared to a valve on demand and a water pH of more than 8.

Subclinical fecal shedding of Salmonella can persist in dairy herds for up to 18 months with no measurable effects on health or production on individual cows. Large herd size and intensive management may provide an environment conducive to Salmonella shedding and chronic dairy herd infection. Salmonella spp. can be isolated from the environment of free stalls in dairy herds in Wisconsin without any history of clinical salmonellosis. Birds that commonly inhabit California dairy farms harbor Salmonella organisms but the low prevalence of infection in birds and the serotypes isolated are not important reservoirs of infection.

The risk factors for fecal shedding of Salmonella in US dairy herds were herd size, region of country, use of flush water systems, and feeding brewers' products to lactating cows. The estimated population attributable risks for all four factors combined was 0.95. These factors can be used to predict the presence of Salmonella shedders in a herd. Salmonella can be isolated from more than 90% of dairy farms but 25% of farms account for more than 75% of Salmonella-positive samples. Concentrating control efforts on farms with a high prevalence may be the most effective means of control of the infection in dairy herds.

The risk factors for becoming a carrier of S. dublin in dairy cattle in Denmark include heifers infected between the age of 1 year of age and first calving, and cows infected around the time of calving. The risk was higher in the first two quarters of the year (late winter to spring). Herds with the highest risk of carrier status were those with a high level of infection of Salmonella on the farm.
carrier development were those with clinical disease outbreaks.

**Beef cattle herds and feedlots**

While salmonellosis can cause significant economic losses in beef herds and feedlots, it is not as important as in dairy cattle. Low numbers of beef cattle are found to shed *Salmonella* at the time of slaughter and beef cattle do not appear to be a major risk of carcass contamination. In Australian cattle, the prevalence of *Salmonella* in the feces of cattle at slaughter was 6.8%. In grass-fed cattle the prevalence was 4.5% and not much different to that found in feedlot cattle. In the US, fewer than 7% of cattle in feedlots shed *Salmonella* in their feces. In European cattle, the prevalence of *Salmonella* in feces has ranged from less than 1% to 42%. *S. montevideo* has been the cause of large economic losses due to abortion and cow mortality in an outwintered beef herd in Scotland. Up to 25% of the cows aborted and the overall herd mortality was 7%. The organism had been the cause of abortion in a neighboring sheep flock.

Case-control studies of risk factors for clinical salmonellosis in cattle herds in Virginia, USA, found that larger herd size, exposure to wild geese, rodent activity in housing and feed areas, and spreading poultry manure on bordering property had positive associations with the occurrence of the disease. Case farms were less likely than control farms to have calves born primarily in a building and had smaller percentage changes in the number of mature cows during the previous year. In contrast, in the UK, farms with housed cattle had increased risk of *S. typhimurium* DT104. Feeding recycled poultry bedding that had been stored and stacked properly for 51 days prior to feeding, to feedlot cattle did not increase the prevalence of detectable *Salmonella* in calves.

Changes in the incidence of shedding *Salmonella* in the feces of cattle being transported from the farm to slaughter plant have been examined. In feedlot cattle, fecal shedding remains fairly constant before and after transport (3–5%); in adult cattle the shedding rate increased from 1% to 21%. Contamination of hides increased for both animal types from 18–20% to 50–56%. Nineteen percent of feedlot cattle carcasses and 54% of adult cattle tested positive for *Salmonella*. Feed withdrawal, transport stress, and the commingling of animals prior to slaughter can affect the number of cattle that are contaminated with bacterial pathogens such as *Salmonella*. However, none of the risk factors evaluated prior to or throughout the transport process had an impact on fecal shedding, hide contamination or carcass contamination. Feedlot playas (temporary shallow lakes) are frequently contaminated with many *Salmonella* serotypes. Using playas as a source of water for feedlots can be a source of *Salmonella* and they should not be used to cool cattle in the summer months, or for dust abatement, or for irrigation of crops. Wildlife, birds, and migratory waterfowl have access to these bodies of water and, because of their size and number, there is little which can be done to prevent them from becoming contaminated.

**Sheep**

Salmonellosis in sheep may occur with a range of different syndromes of variable severity, depending mainly on the particular serovar involved. Serovars *abortivovis*, *dublin*, and *typhimurium*, which each have different degrees of host restriction, are associated with disease in sheep. Serovar *dublin* can cause both enteritis and abortion in adult sheep, and the disease is often associated with metritis, anorexia, and loss of wool. Newborn lambs may develop diarrhea with a high mortality rate. Serovar *typhimurium* is associated with acute disease, enteritis but not usually abortion.

A new strain of *Salmonella brandenburg* has affected livestock and humans in the South Island of New Zealand. The strain has caused abortions in sheep, abortions in cattle and gastroenteritis in calves and adult cattle. The same strain also caused disease in horses, goats, deer, pigs, and humans. Spread of the disease on farms was strongly associated with aborting ewes, which resulted in considerable impact on fecal shedding, hide contamination or carcass contamination.

**Goats**

Outbreaks in goats occur in the same circumstances as in other ruminant species. Transportation and capture are additional stressors in feral goats used for embryo transplantation.

**Pigs**

The epidemiology of *S. choleraesuis* infection in pigs is well documented and has changed remarkably since the mid-1960s, when explosive outbreaks occurred that could easily be mistaken for hog cholera. The morbidity and mortality rates were high and the disease spread rapidly through commercial pig-finishing units. These outbreaks are now rare and small in scope, largely because of the restriction of garbage feeding, much less movement and mixing of pigs through public auction markets, and disease prevention strategies such as the use of specific pathogen-free pigs, an all-in-all-out policy in commercial finishing units, and the vertical integration of pig-producing enterprises. This insures a constant supply of disease-free growing hogs to finishing units and the assumption of a pyramid-type responsibility at all levels of the enterprise. The marked decline in the prevalence of swine salmonellosis coincided with the decline in and eradication of hog cholera. However, modern methods of raising pigs in multiple-site production systems, using all-in-all-out management of finishing pigs, appear to...
Longitudinal studies of *S. typhimurium* infection in farrow-finish pig herds in Denmark reveal that *Salmonella* occurrence varies between and within age groups within herds, even in herds with an apparent moderate-to-high infection level. *Salmonella* was predominant in weaners, growers, and finishers, and was only occasionally detected in sows and gilts. In Denmark, *Salmonella* is typically detected in the nursery and rarely in the sow unit, suggesting that the infection level among sows is low. This is contrary to the results of studies in the USA, where *Salmonella* was found to be common in sows. In the Danish study, there was a rapid increase in *Salmonella* prevalence in the nursery, which may be associated with the stressors of weaning such as change in feed, commingling of litters and piglets being deprived of the antibodies in sow’s milk before activation of their own immune response. The observation that no piglets were shedding *Salmonella* just before weaning but 3–4 weeks later in the nursery between 5% and 50% of the piglets were shedding suggests that horizontal transmission occurred in the nursery. During the finishing period *Salmonella* shedding decreased, but with considerable variation. Some pigs cleared themselves of the infection whereas others continued shedding. Average shedding time was estimated to be 18–26 days. Seroprevalence peaked approximately 60 days after peak prevalence in culture. At slaughter there is a marked increase in the prevalence of *Salmonella* infection. This increase may be due to rapid cross-contamination during transport and lairage. Rapid infection during transport, and particularly during holding, is a major reason for increased *Salmonella* prevalence in pigs. A high degree of carcass contamination occurs at slaughter due to the delivery of *Salmonella*-positive pigs and cross-contamination from the slaughterhouse environment. Contaminated feed trucks may also serve as a potential source of *Salmonella* contamination. The withdrawal of feed from pigs prior to slaughter does not increase the prevalence of *Salmonella* colonization or the risk of carcass contamination.

Risk factors associated with serological *Salmonella* prevalence in finishing pig herds in the Netherlands have been examined. Feeding a complete liquid diet containing fermented byproducts and the omission of disinfection after water pressure washing a compartment as part of an all-in-all-out procedure were both associated with a lower *Salmonella* serorelevance. A small to moderate herd size (<800 finishing pigs), a previous diagnosis of clinical *Salmonella* infection in the herd, the use of tylosin as an antimicrobial growth promoter in finishing feed, and herds that have more than 16% of their pigs’ livers condemned at slaughter because of white spots were associated with a higher *Salmonella* serorelevance. There was no effect on experimental *Salmonella* infection of the use of tylosin as an antimicrobial growth promoter.

In those herds where the disease occurs, introduction is usually associated with the importation of infected carrier pigs. However, it is possible for the infection to be spread by flies and the movement of inanimate objects such as cleaning equipment and utensils. Feed-stuffs do not provide a favorable environment for *S. choleraesuis*, so food-borne infection is not common. Survival in soil and water is approximately 6 months and in slurry up to 5 weeks. Persistence in streams fouled by piggery effluent is unlikely. Susceptibility to salmonellosis in pigs is thought to be increased by intercurrent disease, especially hog cholera, nutritional deficiency of nicotinic acid, and other nutritional stress such as a sudden change in diet.

**Horses**

Based on the culture of single fecal samples from 972 operations in 28 states, the national prevalence of fecal shedding of *Salmonella* spp. among horses in the US horse population was 0.8%. The overall prevalence of operations positive for fecal shedding of *Salmonella* was 0.8%. Based on feed samples taken from the same operations, the prevalence of *Salmonella* spp. in grain and other concentrates used for horse feed was 0.4%.

In adult horses, most clinical salmonellosis occurs after the stress of transport and mostly in horses that are overfed before shipment, receive little or no food or water for the duration of a protracted journey, and are fed excessively on arrival. Cases appear 1–4 days later. Groups of horses that have been exposed to a contaminated environment, such as salesyards or railroad yards, may experience outbreaks in which up to 50% are affected. As with other species, the presence of an asymptomatic carrier in a group of horses is often credited with initiating an outbreak, but the search for the carrier is always laborious and often fruitless. At least five negative clinical examinations of feces should be made before acquiring a suspected donor. On the other hand, the cultural examination of large numbers of horses often reveals up to 50% of the population to be carriers. Multiple serotypes of *S. enteritidis* have been isolated from the mesenteric lymph nodes of 71% of healthy horses examined at an abattoir, which indicates that extraintestinal infection occurs in the horse as it does in other species.

The horse has been recognized as a potential indicator of *Salmonella* presence in feed, water, and the environment.
species. In the light of the high carrier rate in this species it is surprising that there are not more outbreaks.

The occurrence of salmonellosis in horses hospitalized for another disease has become a major problem for veterinary teaching hospitals and private equine practices that provide surgical veterinary care. In these circumstances there is a constant reintroduction of carriers of the disease, a persistent contamination of the environment, and a large population of horses, all of which are under physiological stress because of anesthesia, surgical invasion, or intercurrent disease and many of which are exposed to oral and parenteral treatment with antibiotics, which appears to greatly increase their chances of acquiring salmonellosis. Horses in which nasogastric tubes were passed were at 2.9 times greater risk of having salmonellas isolated than horses that did not undergo this procedure. Horses treated with antibiotics parenterally were at 6.4 times greater risk, and those treated with antibiotics orally and parenterally were at 40 times greater risk of developing salmonellosis, compared with horses not receiving such treatment. In hospitalized horses, the factors found to be associated with fecal shedding of salmonellas included diarrhea at the time of admission, fever while hospitalized, and a change of diet while hospitalized.

The extent of environmental contamination with Salmonella enterica in a veterinary teaching hospital in Colorado was examined. The results indicate that environments in veterinary teaching hospitals can frequently be contaminated with S. enterica where infected animals are managed and fekal specimens containing the bacteria are processed for culture in a laboratory. The bacteriological culture of environmental samples collected with electrostatic wipes is an effective method of detecting contamination in a veterinary teaching hospital and may be beneficial as part of surveillance activity for other veterinary and animal-rearing facilities.

Outbreaks of nosocomial salmonellosis among horses in a veterinary teaching hospital have been described. Case fatality rates may be high, necessitating closure of the hospital for complete disinfection and systematic sampling of the environment to detect the presence of persistent Salmonella. Strict isolation of hospitalized horses that have been shedding Salmonella is necessary. The organisms can be isolated from the feces of hospitalized horses and many different environmental surfaces in the hospital. Salmonella may be detected in 5.5% of hospitalized horses. The planning and implementation of infectious disease control throughout the hospital is then necessary. Bleach is the most effective disinfectant on the largest number of surfaces.

Several variables have been associated with nosocomial Salmonella infections in hospitalized horses. The mean number of horses in the hospital shedding Salmonella krefeld during the first 4 days prior to and the day of admission, the mean number of horses shedding S. typhimurium during this period, a diagnosis of large colon impaction, withholding feed, the number of days fed bran mash, the duration of treatment with potassium penicillin G, and the mean daily ambient temperature.

The factors potentially associated with Salmonella shedding among horses hospitalized for colic at a veterinary teaching hospital were examined. Salmonella spp. were detected in the feces 9% of patients at least once during hospitalization. They were more likely to shed Salmonella if diarrhea was evident 6 hours or less after hospitalization and duration of hospitalization exceeded 8 days (OR 20.3), laminitis developed during hospitalization (OR 12.0), results of nasogastric intubation were abnormal (OR 4.9), leukopenia was evident 6 hours or less after hospitalization (OR 4.6), or travel time to the teaching hospital exceeded 1 hour (OR 3.5). Horses treated with a probiotic did not differ from control horses in likelihood of fecal shedding of Salmonella (OR 1.5) or prevalence of clinical signs.

Occasionally, outbreaks occur in young horses at pasture when they are heavily infested with worms. Salmonellosis is also one of the common neonatal septicemias of foals, and the disease may occur as endemic on particular studs or there may be outbreaks with many foals being affected. The presence of an infective agent in the environment such as slurry as a means of disposal of animal manure that is infested with Salmonella, has been done with being a potential source of infection. Salmonellosis is recognized as a factor contributing significantly to an increase in the new infection rate. A typical example is the carrier rate of 54% observed in intensive pig rearing in New Guinea compared to the 9% in village pigs. A significant change in management of the herd or a group of animals can precipitate the onset of clinical salmonellosis if the infection pre-exists in those animals.

Intensive pasture utilization
The means of infection is principally ingestion of feed, especially pasture, contaminated by the feces of an infected animal, so that the new infection rate is dependent on all those factors that govern the bacterial population in the environment.

Temperature and wetness are most important, as salmonellas are susceptible to drying and sunlight. S. typhimurium can remain viable on pasture and in soil, still water, and feces for up to 7 months. Survival times of the bacteria in soil are influenced by too many variables to make any overall statement meaningful.

As well as infection of pasture by cattle or other domestic animal species, the use of 'slurry' as a means of disposal of animal manure from cow housing or zero grazing areas has led to a highly efficient means of spreading Salmonella infections. The chance of cows becoming infected increases considerably if they are grazed soon after the slurry is applied, and is less likely during dry, sunny periods and when there is sufficient pasture growth to avoid it being eaten right down to the ground surface. The survival time of Salmonella spp. in cold liquid manure depends on several factors, including pH of the slurry and the serotype of the organism. It can be as long as 28 weeks.

Pasture contaminated by human sewage, especially septic tank or sewage plant effluent or sludge, is also credited with being a potential source of Salmonella infection for cattle, but there are a number of reports that do not support this view. Drinking water can remain infected for long periods, as long as 9 months, and in cattle at extensive pasture infected drinking water in stagnant ponds is a significant source of infection.
Housed animals
In housed animals the same factors apply to the spread of infection as apply to
pastured animals. Thus, infection can be introduced by infected domestic animal
carriers. For example, in large-scale calf-rearing units, where the disease is often
of diabolical severity, many of the calves are infected when they are picked up from
their home farms and, if they are penned in groups, all calves in the group are soon
infected. The infection can spread among calves penned individually, which suggests
that aerosol spread may occur. S. typhimurium type 204C can survive for
several months in calf-rearing premises despite depopulation, cleansing, and
disinfection. However, because of the failure of most calves to continue as carriers,
they are usually free of infection within 6 weeks of arrival.

The premixing of food into a liquid form for pumping to feeding stations in
piggeries and calf-rearing units is an effective way of spreading salmonellosis if
infection is present in the feedstuffs and the mix is allowed to stand before feeding. The feeding of medicated milk
replacer and hay to dairy heifers from 24 hours of age until weaning was associated
with a reduced risk of Salmonella shedding, as was calving in an individual
area within a building.

Contaminated feedstuffs
Housed animals are generally more sus-
cceptible to infection from purchased feeds
containing animal byproducts than are
pastured animals, which are again more
susceptible to animal-product-based fer-
ilizers. Organic feedstuffs, including
bonemeal, are being increasingly incri-
mated in the spread of salmonellosis and
although the usual figure, for example in the UK, is 23% of consign-
ments being infected, the figure may be as high as 70%. Most of the contamination of
meat and bonemeal occurs after heat sterilization, especially if the material is
left in digester tanks. Fishmeal is one of
the most frequently and badly contami-
nated feedstuffs. For example, most of
a recent increase in reported isolations of salmonellae in the USA was due to S. agona introduced in Peruvian fish meal.
These feed meals need to be heated at
82°C (180°F) for an hour to be sterilized.
The infection of these materials may derive from antemortem infections in the
animals used to make the byproducts, but soiling of the material at the preparation
plant or abattoir or during storage may also occur. Stored feed not of animal
origin, especially grain, is also commonly
contaminated by the droppings of rodents
that infest it and this can lead to sharp
outbreaks of salmonellosis due to
S. typhimurium. Of special importance is
the colostrum stored without refrigeration. If the colostrum is contaminated initially,
multiplication of salmonellae may occur and transmission of the infection is likely.
Dried milk products appear to be rela-
tively safe.

A case-control study of an outbreak of salmonellosis due to Salmonella menchaden
in dairy herds was associated with one
particular feed mill and feeding animal fat.
Some Salmonella serotypes such as S. typhimurium have been isolated from
2.8% of pig feed and feed ingredient
samples and from 46% of farm feed samples tested. S. choleræus was not isolated from pig feed.

Introduction of the infection to a farm
Contaminated feedstuffs, carrier animals
and infected clothing of visitors and casual
workers are the most common methods of
introducing infection. Less common
methods include free-flying birds such as
the herring gull, and nematode larvae that are already infected with the salmonellae. Salmonellas have been isolated from a
wide variety of wild animals, which could act as reservoirs for infection of domestic
animals under certain conditions.

Pathogen risk factors
Salmonellas are facultative intra-
cellular organisms that survive in the
phagolysosome of macrophages and can
therefore evade the bactericidal effect of
antibody. Compared to other organisms of the same family, salmonellae are
relatively resistant to various environ-
mental factors. They multiply at tempera-
tures between 8°C and 45°C, at water
activities above 0.94, and in a pH range of
4–8. They are also able to multiply in an
environment with a low level of or no
oxygen. The bacterium is sensitive to heat
and will not survive temperatures above
70°C. It is sensitive to pasteurization.
Salmonellas have been shown to be
resistant to drying, even for years, especially
in dried feces, dust and other dry
materials such as feeds and certain foods.
Prolonged survival in water and soil has
also been described. They are quite sensi-
tive to beta- and gamma-irradiation.
The O-antigen lipopolysaccharide of salmonellae is toxic and an important
virulence factor, and immunity directed
against the lipopolysaccharide is thought
to be of major importance in the host
defense against salmonellosis.

Fimbrial antigens of some Salmonella
species have been described and charac-
terized.59 The fimbriae mediate a variety of
virulence factors important for the
maintenance and survival of the organ-
isms in the host and environment, includ-
ing initiation and stabilization of the
organism to epithelial cells, colonization
of the organism to receptor sites, main-
tenance of persistent infection in the host
by mediating selective bacterial trapping
by phagocytic cells, and evasion of the
host's specific immunological defense
mechanisms. The fimbriae are also useful
in diagnostic tests.

Naturally occurring strains with varying
virulence factors and antimicrobial sus-
cceptibility patterns can be identified in
herds with endemic infection. Strains of
S. dublin with distinct antimicrobial sus-
cceptibility patterns and/or plasmid profiles have been repeatedly isolated from calves
in a calf-rearing facility over a period of
years.60 Some of the strains were isolated from
numerous calves during outbreaks of clinical salmonellosis, while other strains were not.

The literature on the molecular basis of
Salmonella-induced enteritis has been reviewed.61 Most of the Salmonella virulence genes have been identified. The effector
proteins of S. typhimurium, which act in concert to induce experimental diarrhea in
calves, have been characterized.62 There
are several differences between S. dublin and S. typhimurium in the phenotypes,
caused by inactivation of genes encoding effecter proteins. The literature on the
molecular methods for epidemiological
investigations of S. enterica infections has been reviewed.63

Antimicrobial resistance of Salmonella
Strains of Salmonella spp. with resistance to antimicrobials are now widespread in
both developed and developing countries.65 Since 1990 there have been dramatic
increases in the occurrence of multiply-
resistant strains of Salmonella spp. in
many developed countries. Of particular
note has been the epidemic spread of
S. typhimurium DT104, which now has a
worldwide distribution. Antimicrobial
resistance in zootonically transmitted salmonellae is an undesirable but almost
inevitable consequence of the use of
antimicrobials in food animals. In general,
such use is legitimate. Recommendations
have been made that new antimicrobials
with cross-resistance to those used in
human medicine should not be used for
prophylaxis in food animal production.
For example, it is argued that the use of
antimicrobials in food animals has been
a major factor in the development of
decreased susceptibility to antibiotics
such as ciprofloxacin in zoonotically
transmitted salmonellae.63

Antimicrobial resistance of salmonellae
has been a major controversial concern in
human medicine and veterinary medicine and human public health.64 Antimicrobials are used in food-
producing animals for the treatment of
infectious diseases and for growth-
promoting effects. Their continued use
has led to the emergence of antibiotic-resistant pathogens in both domestic and
wild animal populations. The evolution of
antibiotic-resistant strains of Salmonella
is a significant public health concern due
to the potential for transmission to humans.
has long been incriminated as a major cause of selective pressure that leads to the appearance and persistence of resistant strains. The resistance is usually to multiple antimicrobials and its existence is considered as a potential risk factor. The significance of antimicrobial resistance is most obvious in its impact on the treatment of human infections. If the frequency of drug resistance increases, the choice of antimicrobials for the treatment of systemic salmonellosis in humans becomes more limited. There is also an association between drug-resistant salmonellas and the routine clinical use of antimicrobials for infections other than salmonellosis. Antimicrobial-resistant Salmonella infections can complicate antimicrobial therapy of other infections; prior antimicrobial therapy allows fewer numbers of antimicrobial-resistant salmonellas to cause symptomatic infections, and an increase in the proportion of salmonellas that are antimicrobial-resistant will increase the overall frequency of salmonellosis. S. enteritidis isolates from horses have developed multiple drug resistance; this is a public health concern.14 Prospectively conducted studies in the USA14 in addition to the resistance to five drugs found in S. typhimurium DT104, S. newport, called Newport MDR-AmpC, is also resistant to amoxicillin-clavulanic acid, cephalothin, cefoxitin, and cefetan and exhibits decreased susceptibility to ceftriaxone. The emergence of Newport MDR-AmpC strains in humans has coincided with the emergence of Newport MDR-AmpC infections in cattle.55 In Massachusetts, the prevalence of the strain among S. newport isolates obtained from humans increased from 0% in 1998 to 53% in 2001. Case-control studies found an association with exposure to a dairy farm. Isolates from both humans and cattle had indistinguishable or closely related antibiograms and pulse-field gel electrophoresis patterns. The data document the widespread emergence of Newport MDR-AmpC strains in the USA and show that the fivefold increase, between 1998 and 2001, in the prevalence of Salmonella resistant to expanded-spectrum cephalosporins is primarily due to the emergence of that MDR-AmpC strain. The strain was isolated from humans, cattle, or ground beef in 27 states.

Molecular epidemiology of cephalosporin-resistant S. newport from animals, animal food products and the environment of animals to each of seven antibiotics – ampicillin, chloramphenicol, kanamycin, neomycin, streptomycin, sulfisoxazole, and tetracycline – increased persistently during each of the years 1994–97 but none of the isolates showed decreased sensitivity to ciprofloxacin.
The prevalence of Salmonella on beef pigs were closely related genotypically, biotics commonly used for the treatment used antimicrobials was low, and high rates of resistance to several antimicrobials was observed. Resistance was not related to the use of antimicrobials in the rations being fed. The prevalence of Salmonella on beef animal hides and carcasses was 15.4% and 1.4%, respectively, and the percentage of isolates resistant to commonly used antimicrobials was low.

The prevalence of S. typhimurium and S. choleraesuis isolates from pigs and humans that are fluoroquinolone-resistant and multi-drug-resistant has increased in Taiwan and the isolates have become widespread across the country. The S. choleraesuis isolates from humans and pigs were closely related genotypically, suggesting the nationwide dissemination of the organism from pigs to humans.

During an 8-year period, 232 Salmonella strains from horses with salmonellosis in the Netherlands were studied. S. typhimurium was the predominant serovar, accounting for 71%, followed by S. enteritidis at 8%. Resistance was common against tetracycline and ampicillin. S. typhimurium DT104 was most frequent and was more resistant to antimicrobials than other serovars, and had the pentadrug resistance pattern of ASST. The most common S. typhimurium phage type in horses corresponded with those found in humans, pigs, and cattle during the same period in the Netherlands.

Zoonotic implications
Salmonellosis, a common human intestinal disorder primarily associated with Salmonella-contaminated meats and poultry, is estimated to cost Americans about US$1 billion or more annually. The Centers for Disease Control report approximately 40,000 confirmed cases of salmonellosis annually. A Canadian study estimated the total cost of salmonellosis in humans at US$100 million per year in Canada; this included hospital and medical costs, lost production, lost leisure, investigating costs and loss of life. Contaminated poultry is a common source of human infection. The cumulative losses are due to medical costs, productivity losses and absenteeism, pain and suffering, lost leisure time, and chronic disease costs. The costs of food safety regulatory programs and costs to the food industry for product recalls and plant closures due to food-borne salmonellosis outbreaks, if included, would also increase the size of the estimates.

The disease has assumed increasing importance in recent years because of the much more frequent occurrence of human salmonellosis, with animal salmonellosis as the principal reservoir. Although transmission to humans does occur via contaminated drinking water, raw milk, and meat, particularly sausage, the important pathway today has become that through pigs and poultry. In Denmark, this was an important source of human salmonellosis until control measures were instituted. In most instances the increase in human infections is with ‘exotic’ serotypes other than S. typhimurium that come by animal feedstuffs to pigs and chicken, and then to humans through pork and chicken products. The most serious risk is that the transmitted bacteria will have acquired resistance to specific antibiotics because the animals from which they originate have been treated with the particular antibiotics repeatedly or over a long period.

An epidemic of salmonellosis associated with S. typhimurium DT 160 in wild birds and humans in New Zealand has been described. Sparrows and other birds usually die of an acute septicaemia and the organism is considered to be a serious zoonotic risk.

The USDA-FSIS issued the Pathogen Reduction: Hazard Analysis and Critical Control Points Systems regulation to encourage effective pathogen reduction systems in meat and poultry processing facilities. This has been successful and is being followed by measures to reduce the numbers of Salmonella entering processing plants through live animals.

Salmonella serovar typhimurium DT104
The increasingly common isolation of S. typhimurium DT104 (definitive phage type) is of major concern for public health officials. S. typhimurium DT104 was first reported in the UK in 1984 and emerged in the 1990s as an increasing cause of Salmonella infections in humans and animals in England, Wales, Scotland, other European countries such as Germany, France, Austria, and Denmark, and Canada. A wide range of potential reservoirs is associated with this infectious strain, from humans to the traditional food animals such as poultry, cattle, sheep, and pigs. Over a 1-year period in Scotland it was the predominant Salmonella isolated from nine species of animal (cattle, pigs, sheep, chickens, pigeons, horses, cats, dogs, and rabbits). All isolates were resistant to at least one antimicrobial and 98% were resistant to multiple antimicrobials, with R-type ACTSp being the predominant resistance pattern. In the UK, a clonal strain of multiply resistant (mr)DT104 that is resistant to at least five antimicrobials (ampicillin, chloramphenicol, streptomycin, sulphonamides, and tetracycline) (R-type ACCSu T) was detected in humans in 1984 and cattle in 1988.

The organism has emerged as an important cause of disease in horses in Ontario and is a public health concern because of its multiple drug resistance and the close relationship of the horse with humans. The organism has been found in a variety of human foods, including salami, sausages, chickens, and eggs, and vegetables. Human infections may result from contact with farm animals (cattle and sheep transmit infections to humans) and from consumption of contaminated foods such as chicken, pork, sausages, meat pastes, and beef. The organism is widespread in the USA. It has been isolated from elementary school children in a Nebraska farming community after they experienced an episode of diarrhea. Farm families are particularly at risk of acquiring infection by contact with infected animals or drinking unpasteurized milk. The organism’s ecology, its precise reservoirs, and its distribution in the human food chain are unclear. Clinical signs in humans infected with DT104 include diarrhea, fever, headache, nausea, and vomiting. Septicemia may develop in a small percentage of cases with potential complications of meningitis and septicemia of bones and joints.

The antimicrobial resistance factor of DT104 is a major concern. Resistance to ampicillin, chloramphenicol, streptomycin, tetracyclines, and sulfoxazole is characteristic of the organism. There is now evidence that DT104 is developing resistance to trimethoprim and fluoroquinolones such as ciprofloxacin, the drug of choice for treating human adult Salmonella infections. A large outbreak of salmonellosis due to DT104 occurred in people in England who had consumed milk from a dairy that received raw milk supplied by two farms. DT104 was isolated from the milk filter and failure of on-farm pasteurization was thought to be the cause. Strains of the organism from humans, the dairy cattle, and the milk filter showed decreased susceptibility to ciprofloxacin.

Control and prevention of infection with DT104 will depend on increasing surveillance activities, investigating outbreaks, and identifying vehicles and risks of infections.

Contamination of milk usually occurs after the milk leaves the cow, even though the organism can be excreted into the milk during...
during the acute phase of the disease, and occasionally by carrier animals. In a Canadian study of families from dairy farms with and without Salmonella-positive bulk tank filters, 41 of 43 of participating families regularly consumed nonpasteurized milk. Of 22 farms with Salmonella-positive milk filters, five had at least one farm family member shedding Salmonella sp. In all cases, the organism shed was of the same serotype, biotype, antimicrobial susceptibility pattern, and plasmid profile as the organism isolated from the filters. Of the individuals in these five families, 63% were shedding Salmonella sp. There is also the chance that contact between animals and humans in agriculture, and in a companion animal relationship, especially with horses, can cause interspecies spread. An unusual but predictable transmission from lambs to humans occurs when sick lambs are fostered, especially by children.

Various clinical forms of salmonellosis can occur in veterinarians working with Salmonella-infected animals. Gastroenteritis, bacteremia and other systemic abnormalities can occur. Cutaneous salmonellosis has been reported in veterinarians attending to infected cattle at the time of parturition. The disease was characterized by pustular dermatitis from which Salmonella virchow and S. dublin were isolated. Veterinarians may develop skin lesions after obstetric deliveries, even after hygienic precautions and the use of abundant amounts of disinfectant creams and careful washing of the arms and hands.

**Economic importance**

Salmonellosis is a significant cause of economic loss in farm animals because of the costs of clinical disease, which include deaths, diagnosis and treatment of clinical cases, diagnostic laboratory costs, the costs of cleaning and disinfection, and the costs of control and prevention. In addition, when the disease is diagnosed in a herd it can create considerable apprehension in the producer because of the difficulty in identifying infected animals. The veterinarian is also often in a difficult position because the diagnosis, treatment, and control of the disease are less than reliable and it is difficult to provide advice with confidence. An estimation of the economic impact of an outbreak of S. dublin infection in a calf-rearing unit indicated that the cost of disease represented a substantial proportion of the gross margin of rearing calves. The losses incurred by livestock producers include reduced feed efficiency, and reduced weight gains or deaths because of salmonellosis.

**PATHOGENESIS**

The pathogenesis of salmonellosis is a complex and multifactorial phenomenon. A range of infections is included in the term 'salmonellosis'. The most common type of infection is known as 'the carrier state', in which carriage of the organism is not accompanied by clinical abnormalities or clinical disease. In production animals, these carriers are of importance because they may serve as reservoirs for further spread of infection through shedding and may be present as contaminated food products.

The evolution of host-specific Salmonella serovars is considered to be associated with an increase in pathogenicity for the specific host. The hypothesis is based on the fact that broad-range serovars (typhimurium and enteritidis) are generally associated with severe disease only in young animals, whereas host-restricted serovars cause high mortality in both young and adult hosts.

The pathogenesis of different Salmonella serovars possessing different degrees of host restriction have been studied in young lambs to evaluate the basis of the serovar-host specificity in sheep. Infection with S. abortusovis resulted in clinical signs of salmonellosis, including a fever and bacterial dissemination to systemic tissues. This confirms the virulence of the strain with sheep. Salmonella gallinarum caused relatively mild disease but is virulent in chickens. S. dublin was virulent in sheep, confirming its association with ovine salmonellosis. The apparent specificity of a serovar for a particular host or range of hosts as defined by epidemiological data is influenced not only by bacterial virulence but also by the ability of the serovar to circulate within the population of the host.

**Infection**

Salmonella infects animals and humans by the oral route. Following ingestion, a proportion of the organisms resist the low pH of the stomach, reach the distal ileum and the cecum, invade the mucosa, and replicate in the submucosa and Peyer's patches.

In young animals, and in adults whose resistance has been lowered, spread beyond the mesenteric lymph nodes occurs and the infection is established in the reticuloendothelial cells of the liver, from there it invades the bloodstream. These steps in the infection process can occur very rapidly. For example, in newborn calves, S. dublin when taken by mouth can be found in the bloodstream 15 minutes later. In older calves bacteria can be isolated from the intestinal lymph nodes 18 hours after their oral administration. Provided a sufficient number of a sufficiently pathogenic serotype is used, the disease is reproducible with pure cultures, for example of S. typhimurium in lambs, S. choleraesuis in pigs, S. dublin, S. typhimurium, and S. enteritidis in calves, and S. typhimurium in horses.

Systemic infection has been established. Salmonellosis as a disease can develop. Its principal manifestations are as septicaemia, enteritis, abortion, and a group of localizations in various tissues as a result of bacteremia.

**Septicemia, bacteremia and the carrier state**

After invasion of the bloodstream occurs a febrile reaction follows in 24–48 hours, and the acute phase of the disease, similar to that seen in natural cases, is present 3–9 days later. The early septicemia may be rapidly fatal. If the systemic invasion is sufficient to cause only a bacteremia, acute enteritis may develop, and abortion is a common final sequel in sheep and cattle. Many animals survive this stage of the disease but localization of the salmonellas occurs in mesenteric lymph nodes, liver, spleen, and particularly the gallbladder. In experimental S. typhimurium infection in pigs, the organism can persist from 6–8 weeks of age until market age with long-term persistence in the palatine tonsils, gastrointestinal tract, and adjacent lymph nodes. In healthy adults there may be no clinical illness when infection first occurs but there may be localization in abdominal viscera. In either instance the animals become chronic carriers and discharge salmonellas intermittently from the gallbladder and foci of infection in the intestinal wall into the feces and occasionally into the milk. For this reason they are important sources of infection for other animals and for humans. Carrier animals may also develop an acute septicaemia or enteritis if their resistance is lowered by environmental stresses or intercurrent infection. Salmonellas can reside intracellularly where they are able to escape antibody-mediated killing, and the numbers of organisms are controlled by cellular defense mechanisms involving the macrophages in which they reside.

Septicaemia in pigs associated with S. choleraesuis can cause pneumonia in pigs similar to the pneumonia in pasteurellosis and infection with Actinobacillus pleuropneumoniae, hepatitis, enterocolitis, and ecephalitis.

S. arizonae may colonize the upper respiratory tract of sheep and induce a mild proliferative response in lambs.

**Enteritis**

Enteritis may develop at the time of first infection or at some other time in carrier animals. The best information available
on the pathogenesis of enteritis is derived from the experimentally produced disease. In most instances the disease is produced by the administration of massive doses of bacteria, and this may result in the production of a different syndrome from that which occurs naturally. The pathogenesis of enteric salmonellosis is much more complex than choler, involving an increase in mucosal cell cyclic AMP content and prostaglandin concentration, as well as an inflammatory response to the invading bacteria. Intestinal invasion is a characteristic feature of Salmonella pathogenesis. Within minutes of injecting ileal loops in calves, Salmonella can be seen to invade both M cells and enterocytes that overlie domed villi associated with lymphoid follicles and absorptive villi. The organism must invade the intestinal mucosal epithelium to cause disease.

*S. typhimurium* requires a functional type III secretion system encoded by *Salmonella* pathogenicity island I (SPII) to cause diarrhea. The SP II secretion system mediates the translocation of secreted effector proteins into target epithelial cells. These effector proteins are key virulence factors required for *Salmonella* invasive intestinal and the induction of fluid secretion and inflammatory responses.

After oral infection with *S. dublin*, invasion occurs through the intestinal wall in the terminal ileum and ceum and progresses as far only as the mesenteric lymph nodes. Progress beyond this point, and the development of the disease, salmonellosis, is determined by factors such as immune status and age of the animal, whether or not it is exposed to stress, and the virulence of the strains. A number of characteristics of the bacteria influence their virulence, including the presence of adhesin-pili and flagellae, cytotoxin, enterotoxin, lipopolysaccharide and the inflammatory response that they initiate in the intestinal wall. The effects of some of these factors are not limited to the intestinal tract and also contribute to the systemic complications of salmonellosis. The *S. dublin* virulence plasmid mediates systemic infection in cattle by causing macrophage dysfunction.

*S. dublin* infections in calves have been used to create the disease experimentally. In calves 6–7 weeks of age, an oral dose of the organisms is fatal within 24 hours, with the animals dying of septicaemia and an acute necrotizing panenteritis. Calves 12–14 weeks of age developed a progressive fatal diarrhoea within 1 week following infection. Experimental infection of ligated ileal loops from calves with *S. typhimurium* results in an acute neutrophilic inflammatory response associated with invasion of Peyer’s patches.

In calves, infection is initiated by bacterial invasion of the mucosal epithelium of the distal ileum or proximal colon causing extensive local tissue damage that leads to shortening of the villi and degeneration of the enterocyte layer. *Salmonella* invasion induces potent inflammatory response characterized by a massive infiltrate of polymorphonuclear cells into the lamina propria and submucosa, and secretion of fluid into the intestinal lumen. Damage to the enterocyte layer and the secretion of fluid into the intestinal lumen results in diarrhoea, and the fever is due to circulating inflammatory cytokines. The molecular basis of *Salmonella*-induced enteritis has been described.

Experimentally induced *Salmonella* infection in calves results in an increase in serum haptoglobin levels within 3 days of challenge. By day 3 after experimental infection the serum haptoglobin levels increased to a median level of 212 μg/mL, while placebo controls had median levels of 0 μg/mL. The increased levels closely reflected the clinical findings of infection and are considered useful markers of infection severity in salmonellosis in calves.

In sheep, the experimental disease produced by oral dosing with *S. typhimurium* includes an early acute enteritis of the small intestine at 24 hours. At 5–8 days there is hemorrhagic and necrotic typhlitis and the infection is established in mesenteric lymph nodes and the liver. Experimental *S. dublin* infection of the mammary gland of dairy cattle results in a persistent infection associated with a chronic active mastitis similar to carriers with naturally acquired *S. dublin* infection.

In ponies with experimental infection with *S. typhimurium* orally, there is much variation in the time after infection that the various signs appear. Pyrexia, neutropenia, and high focal *Salmonella* counts coincided on the second and fourth days, but diarrhoea occurred in only some ponies and then on the third to 11th days after inoculation. Positive agglutination tests were recorded from day 1 but were mostly during the period 6–12 days post-inoculation. The neutropaenia of the early stages of the disease is transient, and neutrophilia occurs when diarrhoea commences.

The characteristic fever and leukopenia of *equine salmonellosis* have been attributed to the release of endotoxin from the bacteria during invasion of, and replication within, the intestinal epithelium. The equine colonic mucosa can respond to cholera toxin, which causes an increased secretion of chloride, sodium, and water into the intestinal lumen. The enterotoxin activity of *S. typhimurium* of equine origin has been compared to cholera enterotoxin.

Although there is sufficient obvious enteritis to account for the diarrhoea that characterizes the disease, there appear to be other factors involved. For example, it has been shown experimentally that in *Salmonella* enteritis there is stimulation of active chloride secretion combined with inhibition of sodium absorption, but invasion of the mucosa is not essential for these changes to occur. These observations are of interest in the light of the known hypotension that characterizes the disease. Studies of calves with salmonellosis have shown that the fluid loss associated with the diarrhoea of this disease is much greater than in other calf diarrhoeas. This, together with a large solid matter output, contributes to the significant weight loss occurring in salmonellosis. In pigs and to a lesser extent in cattle, ulcerative lesions may develop in the intestinal mucosa and may be of sufficient size to cause chronic intermittent diarrhoea. In pigs it has also been observed that villous atrophy is a sequel to infection with *S. choleraesuis*.

In pigs, most clinical cases of salmonellosis are associated with *S. choleraesuis* or *typhimurium*. *S. choleraesuis* is host-adapted to pigs, causing a systemic, typhoid-like disease. *S. typhimurium* is not host-adapted to pigs, and infection results in a localized enterocolitis.

In the pig the development of enteritis associated with *S. choleraesuis* begins 36 hours after infection with the appearance of erosions and edema of the cecal mucosa. At 44 hours the wall is thickened and there is diffuse caseation overlying the erosions. The necrotic membrane sloughs at 96 hours and at 128 hours all function is lost and the entire intestinal wall is involved in the inflammatory process, the muscular coat being obliterated by 176 hours. The colon is usually the major organ affected in *S. typhimurium* infections in pigs, causing either focal or diffuse necrotizing colitis. The organisms proliferate in the intestine, invade the intestinal epithelium, stimulate fluid secretion and disseminate from the intestine to mesenteric lymph nodes and other organs. *S. choleraesuis* invades enterocytes by penetration of the brush border, resulting in focal loss of microvilli, and the bacteria are endocyotised into membrane-bound vacuoles. Experimental infection of ileal–gut loops of pigs with *S. enterica* results in preferential bacterial adherence to microfold cells (M cells) within 5 minutes, and by 10 minutes bacterial invasion of the apical membrane occurs in M cells, goblet cells, and enterocytes. Experimental perfusion of porcine livers with polysaccharide or live
$\text{choleraeuis}$ results in the release of mediators that mediate biological activities that have an important role in reducing the severity of bacterial infections. The comparison between early invasion of ileal loops by $S.\text{enterica}$ and $S.\text{choleraeuis}$ in the pig has been described.99

**Abomasitis**

$S.\text{typhimurium}$ DT104 has been associated with some independent outbreaks of abomasitis in veal calves. Abomasitis was reproduced experimentally by oral infection of calves.

**Abortion**

Abortion is a common manifestation of salmonellosis in cattle between days 124 and 270 of gestation. When infection is associated with $S.\text{dublin}$, the organism multiplies in the placenta, having been seeded there from a primary lesion in other maternal tissues. Fetal death has already occurred in many cases, because of its invasion by bacteria, but live calves also occur, suggesting that the placental lesion is the critical one. $S.\text{montevideo}$ has been associated with a significant number of outbreaks of abortion in ewes.

**Terminal dry gangrene, osteitis, and polyarthritis**

Terminal dry gangrene due to endarteritis of the extremities of the limbs, ears, and tail may occur in calves with $S.\text{dublin}$ infection. Epiphysial osteomylitis affecting the metaphyses, and polysynovitis and arthritis are also possible sequelae.

**CLINICAL FINDINGS**

The disease is most satisfactorily described as three syndromes, classified arbitrarily according to severity as septicemia, acute enteritis, and chronic enteritis. These are described first but the differences between the animal species are sufficiently significant to justify describing the disease separately in each of them. There are no significant differences between infections associated with the different *Salmonella* species.

**Septicemia**

This is the characteristic form of the disease in newborn foals and calves, and in young pigs up to 4 months old. Commonly, there is profound depression, dullness, prostration, high fever (40.5–42°C, 105–107°F) and death within 24–48 hours.

**Acute enteritis**

This is the common form in adult animals of all species. There is a high fever (40–41°C, 104–106°F) with severe, fluid diarrhea, sometimes dysentery, and occasionally tenesmus. The fever often subsides precipitously with the onset of diarrhea. The feces have a putrid smell and contain mucus, sometimes blood, fibrinous casts, which may appear as complete tubular casts of intestine, and intestinal mucosa in sheets or casts. There is complete anorexia but in some cases increased thirst. The heart rate is rapid, the respirations are rapid and shallow and the mucosae are congested. Pregnant animals commonly abort. The case fatality rate without early treatment may reach 75%. In all species, severe dehydration and toxemia occur and the animal loses weight, becomes weak and recumbent, and dies in 2–5 days. Newborn animals that survive the septicemic state usually develop severe enteritis, with diarrhea becoming evident at 12–24 hours after the illness commences. If they survive this stage of the illness, residual polyarthritis or pneumonia may complicate the recovery phase.

**Chronic enteritis**

This is a common form in pigs following a severe outbreak, and occurs occasionally in cattle and adult horses. In calves there is intermittent or persistent diarrhea, with the occasional passage of spots of blood, mucus, and firm fibrinous casts, intermittent moderate fever (39°C, 102°F), and loss of weight leading to emaciation. Although chronic enteritis may occur initially it usually succeeds an acute episode.

**Bovine salmonellosis**

The disease associated with $S.\text{dublin}$ is usually endemic on a particular farm, with sporadic cases occurring when individual animals are exposed to stress. Severe outbreaks are rare but do occur when there is severe stress, usually acute nutritional deprivation, applied to the entire herd.

When $S.\text{typhimurium}$ is the cause, it is usual to have a single animal or a small number of animals affected at one time. When the disease is in the calf population it is usual for it to be much more severe, with many affected, either as a point outbreak or, when there is a succession of calves, a continuing occurrence of the disease. The emphasis, therefore, is generally on the occurrence of individual, sporadic cases in newborn calves and recently calved cows. $S.\text{muenter}$ in a dairy herd has been associated with abortions, diarrhea in adults and calves, and shedding of the organism in the milk of about 8% of the cows.18

**Septicemia** is the common form of the disease in newborn calves under a few weeks of age. There is depression, toxemia, fever, dyspnea, and weakness; nervous signs, including incoordination and nystagmus, may occur. Diarrhea and dysentery may occur but are not common.

Calves older than a week, and adults, are usually affected by *acute enteritis*, followed in survivors by abortion in pregnant cows and polyarthritis in calves. In severe cases of enteritis, there is often dysentery, with whole blood passed in large clots, and complete agalactia in lactating cows. Abdominal pain, with kicking at the abdomen, rolling, crouching, groaning, and looking at the flanks, may occur in adult cattle. Rectal examination at this stage usually causes severe distress.

**Chronic enteritis** with inappetence, reduced weight gain, and unthriftiness may follow an attack of acute enteritis or be the only manifestation of the disease. Abortion is a common sequel in pregnant cows that survive an attack of acute enteritis. However, infection with $S.\text{dublin}$ is also a significant cause of abortion in cattle without there having been any clinical signs other than retained placenta. A sequel to some cases of apparent enteric salmonellosis is the development of terminal dry gangrene due to endarteritis of the extremities, including eartips, tail tip, and the limbs from the fetlock down.

**Terminal dry gangrene of the extremities** of calves is characterized by lameness, swelling of the hindlimbs below the fetlocks, and separation of the skin above the fetlock. The distal portion of the limb is cool, not painful, and the skin is dry or moist. There is a clear line of demarcation of the skin at the level of the fetlock joints between the normal proximal skin and the distal necrotic tissue. The phalanges may be separated and deviated medially and the distal aspect of the tail may be dry and shriveled.

**Abortion** due to $S.\text{dublin}$ may occur spontaneously without any previous clinical evidence of salmonellosis in the herd. Abortion has occurred from days 124 to 270 of gestation. Cows that abort may be ill with a fever, anorexia and hypogalactia and some will retain fetal membranes. In some cases, calves may be born shortly before term and die in the perinatal period. $S.\text{muenter}$ has also been implicated in abortions in a dairy herd.18

The experimental disease produced by infecting adult cattle with $S.\text{dublin}$ by mouth varies from no clinical illness to fatal dysentery. Abortion occurs in some pregnant females. Many suffer pyrexia, anorexia, and mild diarrhea. Experimental infection of calves with $S.\text{typhimurium}$ has the same general effect, with more severe syndromes occurring in younger calves. Chronic cases may develop bone lesions, including osteoarthropathy and osteomyelitis, sometimes with epiphyseal separation. Experimental infection with $S.\text{enteritidis}$ causes profuse yellow diarrhea, fever, dehydration, frequent cough, and a mucopurulent nasal discharge.
Ovine and caprine salmonellosis
The only recognized form of the disease in sheep is acute enteritis on a flock scale. However, in the early stages of the outbreak there may be some cases of the septicemic form. After experimental infection of sheep with *S. dublin*, fever and diarrhea are followed in pregnant ewes by abortion. In goats, naturally occurring cases are not often reported. *S. dublin* is considered more common in sheep than in goats. In sheep in the UK, some ewes die after abortion and many of the lambs born alive die subsequently. Fever and diarrhea, followed by abortion, have also been produced experimentally in sheep by the administration of *S. dublin*.

In goats, naturally occurring cases are not often reported. *S. dublin* is the usual pathogen in those countries where it is a resident, but *S. typhimurium* is also recorded as a cause. Peracute septicemia, abortion, and diarrhea are followed in pregnant ewes by abortion. Abortion is also common in the naturally occurring disease and has come to exceed *S. abortusovis* as a cause of abortion in sheep in the UK. Some ewes die after abortion and many of the lambs born alive die subsequently. Fever and diarrhea, followed by abortion, have also been produced experimentally in sheep by the administration of *S. dublin*.

Porcine salmonellosis
In pigs, the disease varies widely and, although all forms occur in this species, there is often a tendency for one form to be more common in any particular outbreak. In the septicemic form in pigs affected by *S. choleraesuis* a dark red to purple discoloration of the skin is evident, especially on the abdomen and ears, and subcutaneous petechial hemorrhages may also be visible. Nervous signs, including tremor, weakness, paralysis, and convulsions, may be prominent and occur in a large proportion of affected pigs. The case-fatality rate in this form is usually 100%.

A semispecific entity occurring in pigs up to 4 weeks old is manifested by meningitis and clinical signs of prostration and clonic convulsions. In the acute form there is also a tendency for pulmonary involvement to occur, but the main feature of the disease is enteritis, with pneumonia and occasionally encephalitis present as secondary signs. In some situations pigs dying of septicemia more commonly yield *S. choleraesuis*, while those with acute enteritis are usually infected with *S. typhimurium*. Acute pneumonia is a common accompaniment of this form of the disease in pigs, and nervous signs and cutaneous discoloration as described in the septicemic form may also be present. Meningitis due to *S. typhimurium* DT104 in 1-week-old piglets has been reported. Incoordination, paralysis, opisthotonos, paddling, and polyarthritis resulting in runts and deaths were common. Bronchopneumonia resembling Pasteurellosis, and pleuropneumonia resembling A. pleuropneumoniae infection can be associated with *S. choleraesuis* in pigs. A syndrome of rectal stricture occurs in feeder pigs as a sequel to enteric salmonellosis associated with *S. typhimurium* and is described under that heading.

Equine salmonellosis
The disease in horses usually occurs in a single animal and sporadically. However, outbreaks do occur in newborn foals, in groups of horses recently transported, and in horses hospitalized in veterinary clinics. Analysis of spatial and temporal clustering of horses with salmonellosis in an intensive care unit of a veterinary teaching hospital suggested that affected horses were grouped in time. Experimental infection of horses by oral administration of *S. typhimurium* produces a disease similar to the natural disease. The incubation period may be as short as 24 hours. Four syndromes occur:

- **Asymptomatic shedding** of *S. typhimurium* in feces intermittently or continuously for short periods of 4-6 days
- **A subacute enteric form in adult horses** on farms where the disease is endemic, with fever, depression, anorexia but without severe diarrhea, although the feces may have the consistency of soft bovine feces. There is no other obvious intestinal abnormality. There may be a neutropenia with a left shift
- **Severe, acute fulminating enteritis with diarrhea, fever, dehydration, and neutropenia.** There is abdominal pain, which may be sufficiently severe to stimulate violent actions. This is the common form of the disease, occurring commonly in adults that are exposed to stress in one form or another. Newborn and young foals up to 8 days of age also often have this form of the disease, characterized by depression, anorexia, and diarrhea.
- **In foals up to about 2 days of age there is a highly fatal septicaemia.** Localization in survivors includes lesions in the brain, causing meningoencephalitis, polyarthritis, and many other sites. Fatal meningoencephalomyelitis due to *S. agona* has been described in a 7-day-old foal. Clinical findings included head tilt, seizures, and diarrhea.

**CLINICAL PATHOLOGY**
A definitive etiological diagnosis of salmonellosis depends on culture of the organism from feces, blood, milk, and other body fluids or tissues. Feed and water samples may also be cultured to determine the source of the organism. Numerous serological tests are available but lack sensitivity and specificity. The three aspects of cases of salmonellosis that profit by clinicopathological support are:

- Diagnosis in the individual animal, when its treatment and prognosis depend on a definitive diagnosis
- Diagnosis of a herd problem to ensure that expensive herd-wide control measures are not implemented unnecessarily
- Monitoring the biochemical status of a sick animal in order to determine most accurately its requirements for supportive therapy, especially fluid and electrolytes.

The diagnostic techniques available are as follows.

**Bacterial culture and detection**
This is the only way of making a definitive etiological diagnosis of salmonellosis and of exactly determining the serotype. However, culturing the organism is unreliable for various factors including the method used to collect samples, the amount of sample submitted, variation in the shedding of the organism, and the bacteriological method used. A major complicating factor is the occurrence of apparently healthy carriers, which shed the organism intermittently in the feces, and silent carriers, which do not shed but harbor the organism in mesenteric lymph nodes or in the mucosa of the cecum and colon. The difficulty varies according to genotype. In cattle with *S. dublin* infections, the bacteria are present in the blood and milk for a very brief period during the bacteremic phase and before diarrhea commences. The organism can be cultured from fecal samples, bulk tank milk, milk filters, water and feed sources, and environmental sites.

When sampling dairy farms weekly for 7-8 weeks, the prevalence of fecal shedding from different groups of cattle may vary widely among herds, indicating that herds with infected cattle may be classified incorrectly if only one group is tested. Cows near calving are most likely to be shedding *Salmonella* in the feces. Testing environmental sample sources is more efficient for identifying infected premises than using individual cattle fecal samples.

**Fecal culture**
The culturing of salmonellas from feces is done commonly but can be unreliable. This difficulty is noticeable with *S. dublin* infection in cattle, *S. choleraesuis* infections in pigs and *S. typhimurium* infection in horses. The discrepancy in *S. dublin* infections in calves may be so great as 55% accuracy only and in horses only 50%. The difficulties relate to dilution by...
but lack definitive means of control.

The Danish mix-ELISA (DME) is a combination of lipopolysaccharide extraction and ELISA testing. The DME was designed for surveillance and monitoring herds and detecting high levels of Salmonella infection. The test has been used for national Salmonella control programs in Denmark, Germany, and the UK. In a series of studies using pigs experimentally infected with Salmonella typhimurium, the sensitivity of the DME was more than 95% and the specificity 100% when compared to culture used to determine the presence of Salmonella.

Multiple fecal cultures

Multiple cultures at 24-hour intervals are superior to single fecal cultures for the diagnosis of clinical salmonellosis in horses. Fecal samples should be cultured directly on Brucella agar and an additional sample inoculated in Selenite broth and incubated for 24-48 hours followed by culture on Brucella agar. Simultaneous culture of a pinch biopsy of rectal mucosa may increase the number of isolations of salmonellas in cattle and horses.

Antigen-capture enzyme-linked immunosorbent assay

An antigen-capture ELISA with routine culture for detection of salmonellas from fecal samples is more rapid than culture. Multiple fecal cultures followed by culture on Brilliant Green broth may increase the yield of salmonellas from feces collected in a container.

Polymerase chain reaction

A PCR assay is highly specific and sensitive for the detection of salmonellas in fecal samples. The test is genotype specific, much more sensitive than microbiological culture for the organism from fecal swab specimens, and can provide results 24 hours after receipt of fecal samples. Direct detection is done by amplification of part of omp C after extraction of DNA from feces.

DNA probes

The use of the DNA probe encoding a well-conserved virulence gene of the Salmonella virulence plasmid is a sensitive method for screening large numbers of samples to detect potentially virulent Salmonella spp.

Serology

Serum enzyme-linked immunosorbent assay

Serological testing using ELISA tests on serum or milk can be used in herds to identify S. dublin carriers, which can then be culled. The test is based on immunoglobulins to the lipopolysaccharide of the organism. The superior sensitivity and negative predictive value of the serum ELISA is preferable to fecal culture as an initial screening test and for herds not infected with S. dublin. It may be able to differentiate between infected, recently infected recovered, and milk-shedding (mammary-gland-infected) carrier cows; it can also be used for assessing infection rates and vaccine responses. ELISA testing of individual milk samples can be used for surveillance of herds infected with S. typhimurium or S. dublin.

An ELISA test using lipopolysaccharide antigens is highly O-antigen-specific and predictable. A serum with a positive result on the screening antigen can then be tested on the other antigens to determine the specific serotype that has infected the animal. The ELISA is suitable for screening for the presence of infection with S. typhimurium or S. infantis on a herd basis.

Using a variety of ELISA tests, muscle fluid samples from cattle taken at slaughter can be used as an alternative to serum to detect antibodies to Salmonella polysaccharide. Bulk tank milk can be tested for antibodies to S. dublin and used as a national screening diagnostic aid. The S. dublin ELISA had a high sensitivity (97%) and specificity (97%) for muscle fluid samples, compared with serum samples; the relationship for S. typhimurium was also good.

Meat juice enzyme-linked immunosorbent assay: Danish mix-ELISA

The Danish mix-ELISA (DME) is a combination of lipopolysaccharide extraction of S. choleraesuis (O antigens 6 and 7) and S. typhimurium (O antigens 1, 4, 5, and 12), used to assay serum samples collected from live animals on the farm or from meat juice (collected when a meat sample from the carcass is frozen and thawed).

The DME was designed for surveillance and is recommended for monitoring herds and detecting high levels of Salmonella infection. The test has been the basis for national Salmonella control programs in Denmark (SALINPORK), Germany, and the UK. In a series of studies using pigs experimentally infected with Salmonella typhimurium, the sensitivity of the DME was more than 95% and the specificity 100% when compared to culture used to determine the presence of Salmonella.

Diseases associated with Salmonella species

1. Diarrhea and the heavily contaminated nature of the sample; a sample of fluid from a container is superior to a fecal swab. Clinical laboratories generally require at least 48 hours for presumptive diagnosis of Salmonella spp. in feces. Biochemical and serological confirmation of the genotype and the antibiotic sensitivity may require an additional 24-48 hours. The use of extended enrichment of fecal samples with tetrathionate broth is superior to primary enrichment for detection of salmonellas from cattle.

2. A special feature of S. dublin is the tendency to produce persistent infections without clinical manifestations in some infected cattle — also called carriers. The organism is harbored in lymph nodes and other internal organs, and is only periodically shed in milk and/or feces. The rate of fecal culture of S. dublin from known carrier cows and calves is low even when sampled over a period of 12 months — 3.35–17.26%. Carriers frequently have continuously high immunoglobulin levels in serum and milk and ELISAs are used as an alternative.

Because culture of a large number of individual fecal samples is expensive and time-consuming, pooled fecal samples from individual animals provide excellent agreement for detection of S. infantis when the number of samples per pool is 20 or less. With the kappa test, the agreement ranged in two groups of pooled fecal samples from 0.81–0.98.

Multiple fecal cultures

Multiple cultures at 24-hour intervals are superior to single fecal cultures for the diagnosis of clinical salmonellosis in horses. Fecal samples should be cultured directly on Brilliant Green Agar and an additional sample inoculated in Selenite broth and incubated for 24-48 hours followed by culture on Brilliant Green Agar. Simultaneous culture of a pinch biopsy of rectal mucosa may increase the number of isolations of salmonellas in cattle and horses.

Antigen-capture enzyme-linked immunosorbent assay

An antigen-capture ELISA with routine culture for detection of salmonellas from fecal samples is more rapid than routine culture techniques, with a test sensitivity of 69% and specificity of 97%.

Polymerase chain reaction

A PCR assay is highly specific and sensitive for the detection of salmonellas in fecal samples from horses. The test is genotype specific, much more sensitive than microbiological culture for the organism from fecal swab specimens, requires fewer samples, and can provide results 24 hours after receipt of fecal samples. Direct detection is done by amplification of part of omp C after extraction of DNA from feces.

Salmonella DNA was detected in 40% of fecal samples, while Salmonella was cultured from only 2% of the samples. The PCR assay has been used to detect Salmonella DNA persisting in the environment of a veterinary teaching hospital. Pulse-field gel electrophoresis can be used to characterize the types of S. enterica isolate.

A real-time PCR assay uses enrichment of fecal specimens, followed by genomic DNA extraction to detect Salmonella spp.-specific DNA segment. Relative sensitivity was 100% and specificity 98.2% compared with bacterial culture.

Bulk tank milk filters

The bulk tank milk filter is collected immediately after milking and submitted for culture. Samples of bulk tank milk are also submitted.

DNA probes

The use of the DNA probe encoding a well-conserved virulence gene of the Salmonella virulence plasmid is a sensitive method for screening large numbers of samples to detect potentially virulent Salmonella spp.

Serial blood culture

In the early stages of the disease when the animal is likely to be bacteremic this is not a practicable technique because of the need to collect serial samples and the cost of blood cultures.

Serology

Serum enzyme-linked immunosorbent assay

Serological testing using ELISA tests on serum or milk can be used in herds to identify S. dublin carriers, which can then be culled. The test is based on immunoglobulins to the lipopolysaccharide of the organism. The superior sensitivity and negative predictive value of the serum ELISA is preferable to fecal culture as an initial screening test and for herds not infected with S. dublin. It may be able to differentiate between infected, recently infected recovered, and milk-shedding (mammary-gland-infected) carrier cows; it can also be used for assessing infection rates and vaccine responses. ELISA testing of individual milk samples can be used for surveillance of herds infected with S. typhimurium or S. dublin.

An ELISA test using lipopolysaccharide antigens is highly O-antigen-specific and predictable. A serum with a positive result on the screening antigen can then be tested on the other antigens to determine the specific serotype that has infected the animal. The ELISA is suitable for screening for the presence of infection with S. typhimurium or S. infantis on a herd basis.

Using a variety of ELISA tests, muscle fluid samples from cattle taken at slaughter can be used as an alternative to serum to detect antibodies to Salmonella polysaccharide. Bulk tank milk can be tested for antibodies to S. dublin and used as a national screening diagnostic aid.

The S. dublin ELISA had a high sensitivity (97%) and specificity (97%) for muscle fluid samples, compared with serum samples; the relationship for S. typhimurium was also good.

Meat juice enzyme-linked immunosorbent assay: Danish mix-ELISA

The Danish mix-ELISA (DME) is a combination of lipopolysaccharide extraction of S. choleraesuis (O antigens 6 and 7) and S. typhimurium (O antigens 1, 4, 5, and 12), used to assay serum samples collected from live animals on the farm or from meat juice (collected when a meat sample from the carcass is frozen and thawed).

The DME was designed for surveillance and is recommended for monitoring herds and detecting high levels of Salmonella infection. The test has been the basis for national Salmonella control programs in Denmark (SALINPORK), Germany, and the UK. In a series of studies using pigs experimentally infected with Salmonella typhimurium or S. infantis, the sensitivity of the DME was more than 95% and the specificity 100% when compared to culture used to determine the positive or negative status of the pigs.

There is a strong association between herd serology and the prevalence of Salmonella measured at three sampling sites: fecal content, pharynx, and carcass surface.

Indirect tests

These include a total and differential white cell count. A leukopenia, neutropenia and severe degenerative left shift are highly suggestive. There is also a marked hyponatremia and a mild hypokalemia. These tests are well established in horses, and the leukopenia has been observed in acute salmonellosis in cattle. The fecal leukocyte count is also a worthwhile supportive test in the search for salmonellosis. A high count is strongly suggestive, but many horses with acute or severe diarrhea have high fecal leukocyte counts in the absence of salmonellas in the feces.

Laboratory diagnosis in a suspected sick animal

A positive diagnosis depends on culture of the organism, usually from feces but possibly from blood in the septicemic stage. If serological diagnosis is available a serum sample should also be submitted.
Indirect tests are very valuable and, if laboratory availability is good, a total white cell count and estimation of serum sodium levels should be undertaken urgently. A presumptive diagnosis is often all that can be stated, and this may be supported by a herd diagnosis — a diagnosis that the disease or infection is present in the herd and that it is presumed that the subject case is one of the group.

Herd diagnosis
A serological examination of a sample of animals is a first step. A completely negative serological test would indicate that the infection is not present. Positive results indicate a need for further examination, and periodic fecal cultures at 15-day intervals using enriching media should be undertaken. When *S. typhimurium* is the causative bacteria, the feces of other species of animals on the farm should be examined, because ducks, dogs, horses, pigs, sheep, and cattle may be sources of infection for each other. It is always advisable to examine the drinking water and feed for evidence of infection.

Detection of clinically normal carrier animals
The most difficult diagnostic problem in salmonellosis is the detection of the clinically normal carrier animal. The recommended procedure is to do fecal cultures on all cows at 14-day intervals for 3 examinations, and repeat the examination on the day of calving. At that time, swabs are taken from the vagina and the vagina of the cow, and the feces of the calf. The sampling should preferably be done when the cows are tied in stanchions and not grazing pasture, because of the large number of passive carriers of the infection in the latter circumstance.

The reliability of diagnosis based solely on culture of fecal swabs is not high and represents the major difficulty in detecting carriers. A combination of fecal culture and serological tests offers some improvement in accuracy, but even with the agglutination or complement fixation tests accuracy is insufficient.

Determination of prevalence of infection in population of animals
In food-producing animals it is particularly important to determine the prevalence of *Salmonella* infection in a population of cattle or pigs. Pork and pork products are important sources of non-typhoidal *Salmonella* for humans consuming these products if they are not handled with care. Pigs entering the abattoir that are carriers of *Salmonella* are the most important source of carcass and product contamination. In order to be able to estimate the number of infected animals entering the abattoir and estimate the size of the *Salmonella* problem in pig herds, the population and herd level prevalence of *Salmonella* have to be investigated. An estimation of the prevalence of *S. enterica* infection in finishing pigs in Iowa was done using on-farm fecal cultures, culture of on-farm necropsy and abattoir-collected samples, and serum ELISA using serum exudate (meat juice). Fecal samples collected on the farm detected only 13.3% of all positive pigs necropsied on the farm. Abattoir and on-farm results combined, the fecal sample detected 57.4% of positive pigs. Abattoir-collected samples provided prevalence estimates much higher than on-farm collected samples (39.9 vs 5.3%). Thus fecal samples have a low sensitivity for detecting infected pigs and abattoir-collected samples overestimate the on-farm *S. enterica* prevalence. Pigs can become infected during routine testing or holding periods during marketing when exposed to relatively low numbers of *Salmonella* in the preslaughter environment. Intervention this step on the production process may have a major impact on the safety of pork products.

The probability of detecting *Salmonella* in seropositive pig herds and thereby correlation between serological and fecal culture results were examined in pig herds as part of an international research program sponsored by the European Commission, *Salmonella* on Pork. Samples were examined from herds in the Netherlands, Greece, and Germany. The serological herd status was determined by blood-sampling 50 finishing pigs. There was an increased probability of recovering *Salmonella* with increasing within-herd seroprevalence but the correlation was only moderate.

**NECROPSY FINDINGS**

**Septicemia**
There may be no gross lesions in animals that have died peracutely but extensive submucosal and subserosal petechial hemorrhages are usually evident. In pigs, the petechiae are very prominent and may give the kidney the 'turkey-egg' appearance usually associated with hog cholera. A rhomboidal area of gastric mucosal infection is usually present in pigs. Congestion and hepatization of lung tissue may also be present in this species. Skin discoloration is marked in pigs and, depending on the severity of the case, this varies from extreme erythema with hemorrhage, to plaques and circumcised scabby lesions similar to those of swine pox. In some cases the necropsy findings may include splenomegaly and pinpoint white foci in the liver (paratyphoid nodules). The histological lesions are nonspecific, with the exception of the somewhat granulomatous character of the older paratyphoid nodules. The placenta of cattle and sheep aborting due to *Salmonella* spp. often contain very large numbers of intravascular bacteria.

**Acute enteritis**
Some of the changes associated with the septicemic form are often present but the most consistent damage is found in the large and small intestines. The character of the inflammation here varies from a mucointeritis with submucosal petechiation to diffuse hemorrhagic enteritis. Similar lesions may be present in the abomasum, and in *S. dublin* infections in calves multiple mucosal erosions and petechiation of the abomasal wall are common. In porcine enteric salmonellosis, congestion and infarction of the gastric mucosa is often seen. Infections with *S. typhimurium* are characterized by severe necrotic enteritis in the ileum and large intestine. The intestinal contents are watery, have a putrid odor and may contain mucus or whole blood. In cases that have survived for longer periods, superficial necrosis and fibrin exudation may proceed to the development of an extensive diphtheritic pseudomembrane and fibrin casts. The mesenteric lymph nodes are enlarged, edematous, and hemorrhagic. The wall of the gallbladder may be thickened and inflamed. In pigs, survivors of the septicemic and acute enteric forms of salmonellosis may develop rectal strictures.

**Chronic enteritis**
In cattle, the chronic form is usually manifested by discrete areas of necrosis of the wall of the cecum and colon. The wall is thickened and covered with a yellow-gray necrotic material overlying a red, granular mucosal surface. In pigs the lesion is similar but usually more diffuse. Less commonly the lesions are discrete in the form of button ulcers, occurring most frequently in the cecum around the ileocecal valve. The mesenteric lymph nodes and the spleen are swollen. In all species, chronic pneumonia and a variety of other localized inflammatory processes such as polyarthritis and osteomyelitis may be found.

*Salmonellas* are present in the heart, blood, spleen, liver, bile, mesenteric lymph nodes, and intestinal contents in both septicemic and acute enteric forms. In the chronic form, the bacteria may be isolated from the intestinal lesions and less commonly from other viscera. Culture is more successful if enrichment media such as tetrathionate broth are employed. In pigs experimentally infected with *S. typhimurium* and *S. choleraesuis* var. *kunzendorf* the organisms can be detected with peroxidase–antiperoxidase
immunoenzymetric labeling and immunogold techniques. Surveys that set out to determine the percentage of carriers in animal populations by examining abattoir material show that by far the largest number of isolations are made from the lymph nodes draining the cecum and lower small intestine.

**Samples for confirmation of diagnosis**

- Bacteriology – ileocecal lymph node, ileum, colon, spleen, lung, liver, culture swab from gall bladder (CULT)
- Histology – formalin-fixed samples from these tissues plus kidney, stomach, brain (LM).

Note the zoonotic potential of these organisms when handling carcasses and submitting specimens.

### Differential Diagnosis

The clinical diagnosis of salmonellosis is difficult because of the number of other diseases that resemble each form of the disease. Salmonellosis is characterized by septicaemia in young animals and acute and chronic enteritis in adults, although acute enteritis can occur in neonates. Thus the septicaemic form of the disease must be differentiated from all other causes of septicaemia, and the enteric forms from all other causes of diarrhea in both young and adult animals. At necropsy the isolation of salmonellas from tissues and intestinal contents, although suggestive of the presence of salmonellosis, does not of itself confirm the diagnosis, and care must be taken to ascertain whether other disease is present.

**Cattle**

**Septicemia**

The septicaemic form of salmonellosis in calves resembles coliform septicaemia and differentiation is possible only by bacteriological examination of blood, feces, and tissues. Salmonellosis occurs most commonly during the second and third weeks of life in contrast to coliform septicaemia which occurs most commonly in the first few days of life. Both are characterized by weakness, depression, polyneopa, tachycardia, fever or hypothermia, scleral injection and hemorrhages, diarrhea, and rapid death.

**Acute enteritis**

Acute enteric salmonellosis in adult cattle or calves is characterized by fever, anorexia, toxemia, abdominal pain, diarrhea and dysentery, excessive mucus and fibrinous casts and strands in the feces, and dehydration. Septicemic salmonellosis in foals resembles coliform septicaemia and differentiation is possible only by histories of recent transportation often helps in suggesting the diagnosis of salmonellosis in adult horses, in which colitis is important and usually more acute and more highly fatal.

**Horses**

**Septicemia**

Septicemic salmonellosis in foals resembles the septicaemias associated with *E. coli* and *Actinobacillus equuli*.

**Acute enteritis**

Acute enteric salmonellosis in adult horses causes profuse diarrhea, dehydration, severe depression, and weakness. A history of recent transportation often helps in suggesting the diagnosis of salmonellosis in adult horses, in which colitis is important and dehydration and the high case-fatality rate in spite of intensive fluid therapy. Many cases are considered to be enteric salmonellosis but the definitive etiological diagnosis is often not obtained. Other diagnoses that must be considered include:

- **Clostridiosis** due to *Clostridium perfringens* type A, *Clostridium difficile*, may result in peracute hemorrhagic diarrhea, marked dehydration and rapid death.

### Chronic enteritis

Chronic diarrhea due to salmonellosis may resemble parasitism, granulomatous enteritis, or lymphosarcom.

**Pigs**

Septicemic salmonellosis occurs in pigs 1–4 months of age and is characterized by fever, depression, skin color changes, diarrhea, and rapid death.

**Hog cholera, ASF coliform gastroenteritis of recently weaned pigs, and pasteurellosis** may resemble septicaemic salmonellosis closely and laboratory examination is usually necessary for identification.

**Acute erysipelas** is characterized by typical skin lesions, fever, swollen joints, and typical lesions at necropsy.

**Swine dysentery** is characterized by mucoid feces with dysentery and typical lesions of the large intestine.

### Treatment

**Primary treatment – antimicrobial therapy**

The use of antimicrobials for the treatment of clinical salmonellosis is controversial and different approaches to the problem exist among veterinarians. The controversy centers on two parts of the response to treatment, and which view is taken depends on the experience one has with respect to them.

The first issue is that of the success of treatment in saving the lives of clinically affected animals. It is our experience that early treatment with broad-spectrum antimicrobials is highly effective in reducing mortality and returning animals to normal function. It is generally agreed that treatment must be early, because delay means loss of the integrity of the intestine mucosa. A common pattern of response to treatment in a herd is that the first one or two cases are regarded lightly by the owner and they are treated 24–48 hours after diarrhea begins. When these cases die, a more prompt regimen is instituted in which the farmer has the approved drug on-hand and begins treatment as soon as diarrhea with fever is observed. The cure rate is then likely to be of the order of 100%, except in the case of foals and calves, in which a fulminating septicaemia is apt to defeat even the best treatment program.

The second issue in the controversy about antimicrobial therapy for salmonellosis is the risk of inducing ‘carrier’ animals. In humans and in animals there is some evidence that antimicrobials can prolong the duration of the period after clinical recovery during which the causative bacteria can be isolated from
the intestine. It is accepted that this can occur and that the use of antimicrobials can theoretically contribute to the spread of disease. However, because of the way in which animals are kept, and because they constantly ingest contaminated pasture or other feed, there is an almost universal carrier segment in animal populations, and to regard another survivor from salmonellosis as a significant contributor to the carrier frequency seems an exaggeration. In many situations this appears to be the correct view, but in other situations an animal can become infected, for example, in a veterinary hospital or at an exhibition or show, recover clinically with treatment and, after returning to its parent herd, initiate an outbreak of fatal and debilitating salmonellosis. Both epidemiological patterns occur, and they seem to occur in different places, so that the most appropriate attitude to take seems to be the one that fits local circumstances.

In an area where only sporadic cases of the disease occur in herds, it would be professionally negligent not to treat infected animals with appropriate antimicrobials. In endemic areas, recovered animals should not be sent into herds until they are known not to be carriers.

Other related issues are the creation of drug-resistant strains of the bacteria and the effect on the normal intestinal flora that results from oral medication. The problem with resistant strains would not have become a significant one if only individual animals had been treated, but mass medication of in-contact animals and prophylactic treatments have generally resulted in a large population of resistant strains.

Oral treatment in cattle and pigs is recognized as a satisfactory treatment but it is not recommended in horses in which an immediate worsening of the diarrhea, or its prolongation as a persisting chronic disease, may be encountered. It is thought that both sequelae result from an alteration of the normal population of intestinal microflora resulting from the 8–10 times greater concentration of drug that occurs in the intestine after oral treatment, compared to the concentration resulting from parenteral injection.

In summary, antimicrobials are recommended for all clinically affected animals as set out below. The choice of antimicrobials depends on a test of drug sensitivity in each case or outbreak but failing this the following generalizations can be applied.

Ruminants
Currently there are no antimicrobials labeled for treatment of bovine salmonellosis in the USA. As a result, treatment of salmonellosis in cattle is largely empirical and extralab use of certain antimicrobials is common in veterinary practice. Cefotiofur at 5 mg/kg BW intramuscularly/24 hours is effective for the treatment of experimental salmonellosis in neonatal calves. It promotes animal welfare, reduces fecal shedding of Salmonella, and may prolong clearance of Salmonella infections when plasma cefotiofur concentrations are maintained above MICs.

In calves with S. dublin infections trimethoprim–sulfadoxine is recommended, given parenterally daily until clinical recovery occurs. Ampicillin and amoxicillin are also effective. Oral dosing is satisfactory in pre-ruminant calves but it is much less effective when given to grazing ruminants. Trimethoprim and sulfadiazine are very effective for the treatment of experimental salmonellosis in calves with S. dublin. There is marked synergism of the two drugs and both parenteral and oral therapy are effective. Sulfadimidine and franycein are also widely used and recommended. Chloramphenicol was once a commonly used antimicrobial for salmonellosis but is now banned for use in food-producing animals in many countries. Nitrofurazone given orally to calves and adult cattle affected with salmonellosis also was used commonly but is now similarly banned.

Other antimicrobials are the last recourse. Drugs that precipitate attacks of diarrhea. Parenteral treatment with ampicillin or sulfonamide combinations is recommended.

Pigs
For pigs with septicemic salmonellosis, trimethoprim–sulfadoxine is recommended, along with a combination of mass medication of the water supply with chlorotetracline and sulfamethazine (75 mg of each per liter of water). Where large numbers of pigs are affected, mass medication via the feed or drinking water is usually practiced. Because sick pigs do not eat, water treatment is necessary and if drugs are unpalatable individual treatment is the last recourse. Drugs that dissolve readily and are palpable are therefore in demand. Experimental disease of pigs with Salmonella typhiurum can be controlled by the inclusion of low concentrations of chlorotetracline, penicillin, and sulfamethazine in the feed.

Supportive therapy

**Horses**

**Fluid and electrolyte therapy**

In adult horses affected with acute salmonellosis, the dehydration, acidosis and loss of electrolytes are severe. The loss of sodium is most serious, followed by potassium and chloride in that order. A solution of 5% sodium bicarbonate at the rate of 5–8 L/400 kg BW given intravenously over a period of 2 hours as the initial electrolyte replacement therapy will usually help to convert the hyponatremia and acidosis. The hypertonic solution is considered necessary to correct the severe loss of sodium. Following this initial therapy, equal mixtures of isotonic saline (0.9%) and isotonic sodium bicarbonate (1.3%) may be given as maintenance fluid and electrolyte therapy in amounts as indicated. The hypokalemia may be severe in some horses and is recognized clinically by muscular weakness and trembling. It may be corrected by adding potassium chloride to the saline and bicarbonate solution at the rate of 1–2 g/L for a total of 4–6 g of potassium chloride given over 2–4 hours. Concentrated solutions of potassium must be given slowly and the heart monitored for evidence of arrhythmia. However, provided that renal function has been restored, the hyperkalemia that may result from electrolyte therapy or that which could occur following correction of the acidosis should not be hazardous, since the kidney will excrete excess potassium. A safer method would be the oral administration of 30 g of potassium chloride in 8 L of water given twice daily.
Under practical conditions, without the aid of a laboratory for serial evaluation of serum electrolytes, the field veterinarian is faced with using hypertonic solutions as described above or balanced electrolyte solutions and careful clinical monitoring for evidence of overhydration or electrolyte imbalances.

The administration of electrolyte solutions by the oral route is gaining popularity because of the ease of administration and relative safety. Large quantities of fluids (10-30 L) can be administered orally, either all at once, for example in a mature cow, or in smaller quantities (5-10 L) three to four times daily in mature horses. This has been discussed in more detail under fluid therapy in Chapter 2.

**CONTROL**

**Prevention of introduction of infection (biosecurity)**

Avoidance of infection is the major objective but is not easily achieved. The principal sources of infection are carrier animals and contaminated feeds containing foodstuffs of animal origin. There is a critical need to develop methods to control the spread of *Salmonella* infections on dairy farms by instituting biosecurity and biocontainment practices in addition to enhanced farm management. This would result in a reduction in the use of excessive antibiotic treatment of individual animals or herds.

A closed herd minimizes the risk of infection but is not a practicable procedure for the types of animal producer for which salmonellosis is a major problem – the calf-rearer and the commercial pig fattener. For such producers the following rules apply:

- Introduce the animals directly from the farm of origin. Avoid auction marts, salesyards and public transport, all of which are likely to be sources of infection. Insure that the farm of origin is free of salmonellosis.
- If possible, purchase animals when they are older, such as 6 weeks of age for calves, to provide an opportunity for specific and nonspecific immunity to develop. Animals from vaccinated herds are desirable.
- The premises of dealers, salesyards and transport vehicles must be under close surveillance and the need for frequent vigorous disinfection must be stressed. The infection rate in calves delivered to calf-dealers’ yards in the UK was less than 1% but the infection rate increased to 36% if the calves were kept on the premises over the weekend.
- Introduce only those animals likely not to be carriers. Unfortunately the detection of carriers is inaccurate and expensive. To have any confidence in the results, fecal samples for culture must be submitted on at least three occasions. Even then, occasional carriers with lesions in the gallbladder or tonsils will escape the net and be capable of reviving the disease on the farm or transferring it to another one.

For the control of multiple drug-resistant *S. typhimurium* DT104 in cattle herds, the risk factors over which the farmer can exert a level of control and that are effective in reducing the incidence of disease include purchasing replacement stock from direct sources rather than dealers, quarantine of purchased cattle for a 4-week period, housing sick animals in dedicated isolation areas and preventing wild bird access to cattle feed supplies.

Management practices to reduce the risk of *S. brandenburg* on a sheep farm include reducing stocking density; avoiding strip grazing; maintaining adequate nutrition; minimizing yarding of ewes and the time spent in yards; dampening down yards prior to yarding; providing stock with a fresh clean source of drinking water; avoiding the purchase and/or grazing of stock from known affected farms, as they may contain carrier animals; preventing dogs from scavenging; and preventing scavenging by black-backed gulls by removing and burying aborted fetuses frequently during the lambing season.

**Limitation of spread within a herd**

When an outbreak occurs, procedures for limiting spread, as set out below, need to be strictly enforced, and medication of affected groups, and of susceptible groups at high risk, must be carried out. The drugs to be used are those listed under treatment, the choice of the individual drug depending on its efficiency and cost.

- Identify carrier animals and either pull them or isolate and treat them vigorously. Treated animals should be resampled subsequently to determine whether a ‘clean’ status has been achieved.
- The prophylactic use of antimicrobials such as oxytetracycline in the feed at the rate of 10 g/tonne, or chlorotetracycline in the drinking water at the rate of 55 mg/L, is used but not recommended because results are poor and there is a risk of developing resistant strains. Probiotics intended for the prevention of shedding of *Salmonella* in the postoperative period in horses with colic have been evaluated and found to be ineffective.

- Restrict the movement of animals around the farm and limit the infection to the smallest group. Pasture and permanent buildings are both important, although the major source of infection in most cases is the drinking water.
- The water supply should be provided in troughs that are not susceptible to fecal contamination. Static drinking water or pasture may remain infected for as long as 7 months.
- Rigorous disinfection of buildings is important. An all-in/all-out policy should be adopted and steam cleaning and chemical sterilization performed after each batch of animals. Piglets can be reared free of *Salmonella* infections up to 6 weeks of age by removing the piglets from infected herds to isolation facilities when they are weaned at 10–21 days of age. The movement of pigs either at weaning, from the nursery, or from the grower unit to newly built or rigorously cleaned and disinfected finishing units with known history of *Salmonella* infection is highly successful. If economics permit, individual pens for calves are beneficial. Where calves are reared indoors they are common and economical. Pig houses need especially careful treatment. Dirt yards present a problem, especially those used for sheep and calves, but, provided they can be kept dry and empty, two sprayings, 1 month apart, with 5% formalin is recommended.

The control of salmonellosis in veterinary clinics and veterinary teaching hospitals requires special attention to the possible sources of infection and containing and preventing the spread of infection. Following the diagnosis of the disease in a clinic, an environmental survey should be carried out using bacteriological culturing of stalls, wall padding, stomach pumps, nasogastric tubes, alleyways, water drains, and other equipment used routinely. This is followed by a thorough cleaning and disinfection of the entire animal-holding premises. A power water sprayer is used, followed by application of 10% solution of hypochlorite for at least 15 minutes. The surfaces are then recultured to determine the presence of residual contamination. Medical and surgical equipment are cleaned and gas-sterilized. Traffic flow patterns in the clinic are reviewed and modified accordingly. Use of disposable gloves for specific and nonspecific immunity

**Diseases associated with *Salmonella* species**

Salmonella infections in the horse may be caused by *Salmonella typhimurium* or *Salmonella pullorum*. *Salmonella pullorum* is highly infectious and outbreak may occur in young horses. The infection rate in domestic horses in the UK has been reduced from 10% to less than 1% by feeding antibiotics in the foal’s milk. The disease is highly contagious and can be prevented by early vaccination. *Salmonella typhimurium* is less infectious and the disease is usually confined to young animals. Treatment is by administration of antibiotics into the stomach. The disease is often fatal in young animals.

*Salmonella typhimurium* is also found in the drinking water of horses, and this is why the disease is sometimes referred to as "water horse fever". The water supply of horses should be constantly monitored for evidence of contamination. The disease is highly contagious and can be prevented by early vaccination. *Salmonella typhimurium* is less infectious and the disease is usually confined to young animals. Treatment is by administration of antibiotics into the stomach. The disease is often fatal in young animals.

and thorough washing of hands after handling suspect animals are recommended. Stalls in which horses with salmonellosis were housed should only be used to accommodate newly hospitalized horses after sample (collected after two cycles of cleaning and disinfection) from stall drains, cracks and corners yield negative results on bacteriological culture. Using PCR assay for Salmonella DNA, samples from floor drains and drainpipes yield the greatest proportion of positive results. The PCR results should be confirmed by bacteriological culture because a positive PCR in itself is not considered to pose a risk of salmonellosis to hospitalized horses. When a hospitalized horse leaves its stall permanently, it should be cleaned of organic matter using a cold water hose and scrubbed with a steel wool mop. This is followed by an application of generic bleach solution. This is then followed 24 hours later by another cleaning and disinfection with a peroxide solution (Virkon) and allowed to dry. Virkon is a balanced stabilized blend of peroxide compounds, surfactants, organic acids, and inorganic buffer system. Active ingredients are potassium peroxymonosulfate, sodium chloride, and other ingredients. It is effective against a wide range of bacteria, virus, and fungi, including Streptococcus pyogenes, Campylobacter pyloridis, Klebsiella pneumoniae, E. coli, and S. typhimurium.

Suitable construction of housing is important. Impervious walls to stop spread from pen to pen, pen design to permit feeding without entering the pen, avoidance of any communal activity and slatted floors to provide escape routes for manure all assist in limiting the spread of enteric diseases. Deep litter systems are satisfactory provided they are kept dry and plenty of bedding is available. With pigs the opportunity for oral–fecal cycling of the organism and buildup and spread of infection within and between groups must be kept to a minimum. Pen design and the environment should be such as to encourage proper eliminative behavior and good pen hygiene. Drinkers should be sited at one end of the pen, preferably on a narrow end with oblong pens, to encourage defecation in this area. Wet or damp areas of the floor in other parts of the pen will encourage defecation and urination there and should be eliminated. Drinkers of the nipple type rather than bowls are preferable for hygienic reasons. Communal dunging alleys increase the possibility of spread, especially during the cleaning procedure, and the trend is towards slatted or meshed areas over a channel. A totally slatted or mesh floor for pigs from weaning until 10–12 weeks of age will markedly reduce the opportunity of oral–fecal cycling of organisms in this age group, which is especially susceptible to enteric disease. Feeders should allow the ingress of the pig’s head and should be constructed to avoid fecal and other contamination of feed. Pigs need to be grouped according to size, and overcrowding, which may result in improper pen hygiene, must be avoided. Space requirements vary according to pen and housing design but generally fall in the region of 0.3 m² for recently weaned piglets to 0.6–1 m² for market-size pigs. In conventionally floored or partially slatted floored pens, approximately two-sevenths of the area should be available for the dunging area. The construction of the pen should allow for easy and efficient cleaning. In problem herds an especial vigilance for the occurrence of enteric disease is needed following the breakdown of pen hygiene on very hot days.

Heat treatment of feed is an effective procedure for pigs. Heating during pelleting greatly reduces the bacterial content of feed and special treatment is worthwhile because of the very high proportion of animal-derived feeds that are infected. The availability of such feeds guaranteed to be Salmonella-free would be an advantage.

Disposal of infective material should be done with care. Carcases should be burned or, better still, sent to an institution for diagnosis, rather than to a rendering plant to be converted into still more contaminated bone meal. Slurry and manure for disposal should be placed on crops rather than on pasture. Slurry does not constitute a danger via hay, and salmonellas do not survive silage making. When slurry is used on pasture it should be stored for at least a month beforehand and even longer if silo effluent is included. Slurried pasture should not be grazed for 1 month, and for young animals a 6-month delay is recommended. Pig slurry is most dangerous and should always be avoided.

All persons working on infected premises should be warned of the hazards to their own health. Other peripatetic species, especially dogs, should be kept under close restraint.

Principles of infectious disease control for prevention of nosocomial gastrointestinal and respiratory diseases in large-animal hospitals

The principles of an infectious disease control (IDC) program for the prevention of gastrointestinal and respiratory diseases in a large-animal hospital have been described and are applicable to the control of salmonellosis. The three basic strategies are reducing exposure to pathogens, avoiding increasing susceptibility to pathogens, and monitoring effectiveness of the IDC program. The major procedures are summarized here.

Reducing exposure to pathogens
- Promoting appropriate personal hygiene
- Using effective methods for cleaning and disinfection
- Controlling the flow of human and animal traffic
- Implementing protocols for prompt identification of patients with signs of contagious disease
- Controlling birds, rodents, and flies.

Avoiding increasing susceptibility to pathogens
- Controlling ambient temperature
- Using antimicrobials appropriately
- Aiding in establishing normal intestinal or rumen flora
- Controlling endotoxemia.

Monitoring effectiveness of the infectious disease control program
- Bacterial culture of fecal samples of animals admitted to the hospital
- Regular culture of environmental samples.

Recommended steps in developing an effective infectious disease control program (IDC) for a large-animal hospital

An effective IDC program is necessary for all large-animal veterinary teaching hospitals and private veterinary clinics. The recommended steps are outlined here:

- Have all clinicians work together to develop and approve the IDC program, as grassroots buy-in is vital
- Develop a specific, written IDC program and disseminate it widely among staff members
- Identify a veterinarian who is active in the large-animal hospital to serve as the IDC officer; this individual will oversee the IDC program and should report to the hospital director and practice partners
- Provide the resources, both human and monetary, needed for the IDC officer to effectively carry out the

approved IDC program; prevention costs less than the alternatives

- Make students, residents, and staff aware of the key points of the IDC program and the importance that clinicians place on compliance
- Teach the barn crew, particularly those actually responsible for cleaning, disinfecting and feeding, about the goals of the IDC program and the methods to be used
- Monitor the effectiveness of cleaning and sanitation by means of bacterial culture of environmental samples and give regular feedback to the barn crew, staff, students, and clinicians
- Hold a seminar at least yearly to distribute written information about the IDC program and results of monitoring.

**Animals being transported**

These are a special case. They should be unloaded or exercised at least once every 24 hours and given water and feed, the feed being provided first and at least 2 hours before watering. Hay or chopped hay is preferred to succulent feeds. All railroad cars and feeding and watering troughs should be properly cleaned and disinfected between shipments. Horses that are to be transported should be yarded and hand-fed on hard feed for 4-5 days beforehand. If the disease is likely to occur, prophylactic feeding with sulfonamides or antimicrobials has been shown to decrease the incidence in all species. Apart from the risk that this practice will produce resistant bacteria, there has been a suggestion that it may so change the normal bacterial flora of the gut as to encourage the proliferation of salmonellas and lead to the development of the clinical disease.

**Immunization**

*Salmoneil a* vaccinology

The literature on *Salmonella* vaccines has been reviewed. Host resistance to *Salmonella* relies initially on the production of inflammatory cytokines leading to the infiltration of activated inflammatory cells in the tissues. Thereafter, T- and B-cell-dependent specific immunity develops, allowing the clearance of *Salmonella* from the tissues and the establishment of long-lasting acquired immunity to reinfection. The increased resistance that develops after primary infection or vaccination requires T cells, cytokines such as interferon gamma, tumor necrosis factor and interleukin 2, in addition to opsonizing antibody. Serovar conversion and/or the presence of detectable T-cell memory do not always correlate with the development of acquired resistance to infection.

Immunization with live salmonellas induces early resistance rechallenge with virulent organisms that appears 1 day after infection or vaccination with live but not killed organisms. Early protection is nonspecific and effective against different *Salmonella* serotypes. Long-term immunity using live attenuated vaccines is serotype-specific and involves the recall of immunological immunity. Killed vaccines induce strong antibody responses but trigger insufficient T-helper 1 (Th1)-cell responses.

Vaccination can decrease the number of bacteria shed in feces and the number of blood-culture-positive calves, thus decreasing the number of carriers and reducing environmental contamination. Many types of vaccines have been developed and tested in cattle and pigs. If vaccination is combined with the hygienic precautions described, the vaccines are an aid to management. Killed bacterins and live attenuated vaccines are available. Either can be used as a prenatal vaccine to provide passive immunization of the newborn. It is now generally accepted that live *Salmonella* vaccines are more effective immunogens in calves than are killed vaccines.

**Cattle**

In cattle, *S. dublin* is the infection likely to be endemic in a herd and a commercial vaccine, to be effective, must have a strong *S. dublin* component. Live organisms are better able to stimulate antilipopolysaccharide antibodies and to stimulate cell-mediated immunity. Calves vaccinated at 1-3 weeks of age with a modified-live, aromatic-dependent *S. dublin* bacterin have detectable antilipopolysaccharide immunoglobulins after immunization. Safe live oral vaccines against *S. typhimurium* and *S. dublin* have been constructed and shown to confer protection against experimental infection with virulent wild-type strains of the organism. Vaccination of calves orally with a genetically altered stable nonreverting *aro-S. dublin* as a modified-live vaccine provided a measurable systemic immune response but the vaccine volume makes it unlikely to be practical for field use. Vaccinated calves responded with increases in humoral-mediated immunity and cell-mediated immunity, as measured by ELISA and skin testing. It is claimed that the combination of humoral immunity and cell-mediated immunity stimulated by live-organism vaccines provides superior protection. Other genetically altered vaccines consisting of hybrid strains derived from *S. dublin* and *S. typhimurium* are being evaluated. An avirulent live *S. choleraesuis* vaccine is efficacious experimentally against salmonellosis due to *S. dublin* infection in calves.

The vaccine strain 51, produced in the UK from a rough variant strain of this organism, has been found to be efficient and safe, and provides good protection against *S. typhimurium* as well as *S. dublin*. It has the disadvantages of a living vaccine but calves can be vaccinated successfully at 2-4 weeks of age. In limited experiments other living, attenuated and killed, adjuvanted vaccines have given calves protection, and a comprehensive program of vaccination, hygiene, and adoption of a closed herd policy has been successful in controlling the disease. Reports on killed *S. typhimurium* vaccines used in calves indicated good results provided the antigenic mass in the vaccine is kept high, but commercial killed vaccines are of doubtful value.

Attenuated *S. typhimurium* (strain SL1479) given orally or intramuscularly has shown good efficacy, and attenuated *S. dublin* (strain SL1438) has been similarly effective. The *S. typhimurium* vaccine also gives some protection against *S. dublin*.

The autogenous bacterin, which must be precipitated on aluminum hydroxide to have any significant effect, is given as two injections 2 weeks apart. Good immunity is produced but calves and pigs less than 6 weeks of age are refractory, and anaphylactic reactions may cause the loss of a significant number of animals. To protect young calves the best program is to vaccinate the cows during late pregnancy. This will give passive protection to the calves for 6 weeks, provided they take sufficient colostrum, and the calves can be vaccinated at that time if danger still exists. Vaccination of pregnant cattle with a formalin-killed *S. typhimurium* vaccine approximately 7 and 2 weeks before parturition protected their calves against experimental infection. Reports of results have not been enthusiastic but if proper attention is given to the detail of the program it has been sufficient, in our hands, to provide almost complete protection. A similar observation has been made with respect to vaccination of calves against *S. typhimurium*.

**Pigs**

A commercial vaccine containing living, attenuated *S. choleraesuis* has also been shown to protect neonatal pigs after vaccination of sows and weaned pigs. Because of the early age at which pigs need to be immune, it is recommended that sows be vaccinated three times at 7-14 day intervals. The young pigs are vaccinated at 3 weeks of age. A live avirulent *S. choleraesuis* vaccine has been developed and evaluated for protection against experimental challenge. Vaccinated pigs were able to maintain normal body weight gains during a 4-week observation period following challenge inoculation with a high dose of a virulent strain. It has
consistently been safe and efficacious in pigs as young as 3 weeks and provides protection for at least 20 weeks.

Most cases of salmonellosis in pigs are subclinical and due to *S. typhimurium*. The ideal vaccine against *S. typhimurium* would prevent colonization, shedding of the organism in the environment, development of carriers and clinical salmonellosis, and promote elimination of the organism from infected animals. Livestock vaccine strains are considered to provide superior protection compared to inactivated vaccines.

Livestock results in sheep have been unconvincing. Some live *S. typhimurium* vaccines are being evaluated for their efficacy against salmonellosis in sheep.

**Nationwide surveillance and control programs**

In 1993, the Ministry of Food, Agriculture and Fisheries of Denmark and the Danish Bacon and Meat Council initiated an ambitious program to eliminate pork as an important source of human salmonellosis. In the early 1990s pork had become recognized as an increasingly important source of human salmonellosis in Denmark. In Denmark, the proportion of human salmonellosis attributable to pork was estimated to be 10–15% in 1997 and 1998. In the Netherlands, it was estimated that approximately 15% of human cases of salmonellosis were associated with the consumption of contaminated pork.

The Danish Salmonella Surveillance and Control Program for pigs operates at all stages of the production chain and has been applied nationally since 1995. As a result of the program the level of *Salmonella* in Danish pork declined from 3.5% in 1993 to 0.7% in 2000. Simultaneously, the number of human cases of salmonellosis due to pork declined from approximately 1444 in 1993 to 166 in 2000.

The control program is integrated from 'feed to food'. It is based on routine testing and classification of slaughter pig herds and subsequent slaughter of pigs according to the inherent risk, as measured by the continual test program.

Basic activity of the program is the testing of meat-juice samples collected during routine testing in all plants producing animal feeds. The proportion of serologically positive meat-juice samples collected during the previous 3 months. Based on the optical density per cent (OD%) of the ELISA test, the herds are classified into:

- **Level 0**: Herds having only seronegative over 3 months or more
- **Level 1**: Herds with acceptable low *Salmonella* prevalence
- **Level 2**: Herds with moderate *Salmonella* prevalence
- **Level 3**: Herds with unacceptable high *Salmonella* prevalence.

A herd categorized as level 2 or 3 must receive an advisory visit by a practicing veterinarian and a local extension specialist, and certain management precautions must be adopted. In a herd with level 3, the finishing pigs must be slaughtered under special hygiene conditions.

The proportion of serologically positive meat-juice samples collected during 1995 ranged from a mean of 2.9% in small herds to 6.1% in large herds.

**Feedstuffs**

Compounded feeds are heat treated at 81°C to eliminate *Salmonella*. The national program requires mandatory *Salmonella* testing in all plants producing animal feeds. In 2000, the level of *Salmonella* spp. in final products was only 0.3%.

**Breeder and multiplier herds**

Each month all herds are blood sampled and examined for *Salmonella* antibodies. Based on the level of antibodies, a *Salmonella* index is calculated. If the index exceeds 5, pen fecal samples must be taken and examined for the presence of *Salmonella* spp. When the index exceeds 15, a sales ban on breeding pigs is imposed until the index has declined below 15 again.

**Weaner producers**

If a sow herd sells weaners to a *Salmonella* level 2 or 3 finishing herd, pen fecal samples must be taken and examined for *Salmonella*.

**Slaughter pigs**

Slaughter pig herds are monitored continuously by serological testing of 'meat juice'. Meat samples are frozen, and meat juice (harvested after thawing) is examined for specific antibodies against *S. enterica* using an ELISA. The ELISA combines several *S. enterica* O antigens and allows detection of antibody response after a variety of serovar infections. The meat samples for testing are collected at the slaughter line, and the number of samples and frequency of sampling are determined by the size of the herd. Herds sending fewer than 200 pigs to slaughter per year are not examined, which amounts to 1.6% of slaughter pigs not examined. The herds are categorized in four levels based on the proportion of seropositive meat juice samples during the previous 3 months. Based on the optical density per cent (OD%) of the ELISA test, the herds are classified into:

- **Level 0**: Herds having only seronegative over 3 months or more
- **Level 1**: Herds with acceptable low *Salmonella* prevalence
- **Level 2**: Herds with moderate *Salmonella* prevalence
- **Level 3**: Herds with unacceptable high *Salmonella* prevalence.

A herd categorized as level 2 or 3 must receive an advisory visit by a practicing veterinarian and a local extension specialist, and certain management precautions must be adopted. In a herd with level 3, the finishing pigs must be slaughtered under special hygiene conditions.

The proportion of serologically positive meat-juice samples collected during 1995 ranged from a mean of 2.9% in small herds to 6.1% in large herds.
lesions in males and septicemia in the newborn.

ETIOLOGY

Salmonella abortus equi (abortivoequina) (also known as Salmonella enterica serovar abortus equi) is a host-adapted serovar causing abortion in mares and donkeys.12 S. abortus equi strains vary in virulence, with more virulent strains having greater in vitro cytotoxicity.7 It is possible to determine the origin and progression of outbreaks of the disease by determining pulsed-field gel electrophoretic patterns of S. abortus equi.2

EPIDEMIOLOGY

The infection appears to be limited to horses and donkeys.24 Although widely reported in the early 1900s, this disease is rarely encountered nowadays and is one of the less common causes of either abortion or septicemia in horses.25 Recent reports of the disease are from Austria, Brazil, Croatia, Japan, and India, although the disease occurs in other countries. However, in the early 1990s, an outbreak of abortion occurred in a herd of 38 horses, in which 21 mares aborted between 5 and 10 months of gestation.3

Natural infection may be due to the ingestion of foodstuffs contaminated by uterine discharges from carriers or mares that have recently aborted. Transmission from the stallion at the time of service is also thought to occur. The infection may persist in the uterus and cause repeated abortion or infection of subsequent foals. Transmission from a female donkey to mares is reported to result from abortion in both species.2

PATHOGENESIS

When infection occurs by ingestion, a transient bacteremia without marked systemic signs is followed by localization in the placenta, resulting in placentitis and abortion. Foals that are carried to term probably become infected in utero or soon after birth by ingestion from the contaminated teat surface or through the umbilicus.3

CLINICAL FINDINGS

Abortion usually occurs at about the seventh or eighth month of pregnancy. The mare can show signs of impending abortion followed by difficult parturition but other evidence of illness is usually lacking. Retention of the placenta and metritis are common sequelae and may cause serious illness, but subsequent sterility is unusual. A foal that is carried to term probably becomes infected in utero or soon after birth by ingestion from the contaminated teat surface or through the umbilicus.

REFERENCES

Infection in the stallion has also been reported, clinical signs including fever, edematous swelling of the prepuse and scrotum, and arthritis. Hydrocele, epidermitis, and inflammation of the tunica vaginalis are followed by orchitis and testicular atrophy.

CLINICAL PATHOLOGY
The organism can be isolated from the placenta, the uterine discharge, the aborted foal, and the joints of foals with polyarthritis. A high titer of Salmonella agglutinins in the mare develops about 2 weeks after abortion. Vaccinated mares will give a positive reaction for up to a year.

NECROPSY FINDINGS
The placenta of the aborted foal is edematous and hemorrhagic and may have areas of necrosis. The nonspecific changes of acute septicemia will be manifested in foals dying soon after birth; polyarthritis is found in those dying at a later stage.

Samples for confirmation of diagnosis
- Bacteriology – placenta, fetal stomach content, lung, culture swabs of joints (CULT)
- Histology – formalin-fixed placenta, various fetal tissues including lung, liver (LM).

TREATMENT
The antimicrobials recommended in the treatment of salmonellosis should also be effective in this disease.

CONTROL
Careful hygiene, including isolation of infected mares and disposal of aborted material, should be practiced to avoid spread of the infection. Infected stallions should not be used for breeding. In the past, when this disease was much more common, great reliance was placed on vaccination as a control measure. An autogenous or commercial bacterial, composed of killed S. aborto-ovis organism, was injected on three occasions at weekly intervals to all mares on farms where the disease was enzootic, commencing 2–3 months after the close of the breeding season. A smaller dose (5 mL) of vaccine of higher concentration is as effective as a larger dose (20 mL) of vaccine of lower concentration. A formalin-killed, alum-precipitated vaccine is considered to be superior to a heat-killed, phenolized vaccine. In China a virulent strain vaccine is credited with effective protection after two injections 6 months apart. The widespread use of vaccines and hyperimmune sera is credited with the almost complete eradication of the disease in developed countries.

ABORTION IN EWES ASSOCIATED WITH SALMONELLA ABORTUSOVIS
Salmonella abortusovis (S. enterica serovar abortusovis) is a relatively uncommon cause of abortion in ewes but appears to be enzootic in particular areas. Spread of the disease may occur after introduction of carrier animals. The reservoir of infection is infected animals that do not abort. The organisms persist in internal organs of the carrier for up to 6 months, and are excreted in the feces and vaginal discharge for periods up to 4 months. Ingestion is thought to be the main mode of infection. The experimental disease induced by the conjunctival route has been examined. Venereal spread has been postulated, and rams certainly become infected, but all the evidence is against spread at coitus. Experimental induction of the disease in ewes is more successful after the third month of pregnancy. Intrapleural inoculation results in infection of rams and the passage of infected semen for up to 15 days. Abortion ‘storms’, with up to 10% of ewes aborting, occur about 6 weeks before lambing, and septic metritis and peritonitis subsequently cause a few deaths among the ewes. Mortality in lambs is common due either to death of weak lambs or to the development of acute pneumonia in previously healthy lambs up to 2 weeks old.

Identification of the disease depends upon isolation of the organism, which is present in large numbers in the fetus, placenta and uterine discharges, and the presence of a strong positive agglutination test in the ewe for 8–10 weeks after abortion. An ELISA test detects antibody to S. abortusovis in a greater proportion of sheep than does a microagglutination test. The disease can be diagnosed in fetuses by use of a coagulation test on fetal stomach contents. The test had a sensitivity and specificity of 100% and 90% in a small number of samples. Use of PCR to identify S. abortusovis is feasible because the organism has an IS200 element in a distinct chromosomal location. The resulting PCR assay has high specificity for S. abortusovis, effectively discriminating it from other S. enterica serovars.

The clinical and serological findings in S. dublin infections in ewes are very similar, and infection has become more important as a cause of abortion in ewes in the UK than S. abortusovis. A strong immunity develops after an attack and an autogenous vaccine has given good results in the control of the disease. The results of vaccination need to be very carefully appraised because flock immunity develops readily and the disease tends to subside naturally in the second year.

Salmonella nutrii has also been recorded as a cause of abortion in ewes, and ewes with salmonellosis associated with S. typhimurium may also lose their lambs. S. brandenburg is a cause of illness and abortion in sheep, horses, calves, goats, and humans in New Zealand. Spread of the disease is strongly associated with presence of aborting ewes and subsequent heavy environmental contamination.

The administration of broad-spectrum antibiotics might aid in controlling an outbreak but available reports are not generally encouraging. Chloramphenicol, and trimethoprim and sulfadiazine combination are considered effective for treatment but use of chloramphenicol in animals intended for use as human food is not permitted in many countries. A live S. typhimurium vaccine with optimal level of attenuation for sheep constructed by means of “metabolic drift” mutations was highly effective in preventing S. abortusovis-induced abortions under field trial conditions. Subcutaneous and conjunctival vaccination with a live attenuated strain of S. abortusovis confers immunity for at least 15 lambing periods. More recent vaccines, including those containing plasmid-cured strains of S. abortusovis, are being developed to prevent pregnancy loss in response to experimental challenge with wild-type S. abortusovis.

REVIEW LITERATURE

REFERENCES
Diseases associated with *Pasteurella* species

*Pasteurella* species occur in many animal diseases and, although in some instances they act as primary causes, the number of conditions in which they appear to play only a secondary role is gradually increasing. However, their importance is not insignificant. A primary viral pneumonia may be an insignificant disease until the intervention of a secondary *pasteurellosis* converts it into an outbreak of pneumonia of major economic importance. The common diseases in which *Pasteurella* spp. play an important etiological role are described in this section with due regard to their possible secondary nature. Mastitis associated with *Pasteurella* spp. is dealt with in the section on mastitis. There is now general agreement that atrophic rhinitis in pigs is associated with toxigenic strains of *Pasteurella multocida*.

The bovine strains of *P. multocida* have been characterized and compared with isolates of avian, ovine, and porcine origin. *P. multocida* is a heterogeneous species of Gram-negative bacteria and is a commensal of the upper respiratory tract of many animal species. Under certain predisposing conditions the organism is the etiological agent of a wide range of economically important infections in domesticated animals. The pathogen consists of five capsular subgroups, A, B, D, E, and F, and there is a relationship between the capsular subgroup and disease predilection. *P. multocida* is responsible for two major disease conditions of cattle: hemorraghic septicemia and pneumonic *pasteurellosis*. Hemorrhagic septicemia occurs almost exclusively in cattle and water buffalo in Asia and Africa and is associated with *P. multocida* strains of capsular serogroups B and E. In contrast, pneumonic *pasteurellosis* is an important infectious disease of cattle in Europe and North America and, in addition to *Mannheimia haemolytica*, is associated mainly with *P. multocida* strains of capsular serogroup A. *P. multocida* is also occasionally the cause of mastitis, abortion and localized infections in cattle such as otitis externa.

There is a limited degree of strain diversity among bovine disease isolates of *P. multocida*. Comparison of the outer membrane profiles of bovine isolates with those of avian, ovine, and porcine strains indicate that a high proportion of the respiratory tract infections in each of these species are associated with different strains. However, the presence of small numbers of closely related strains in more than one host species suggests that transmission of bacteria between different host species is also a factor in the population biology of *P. multocida*.

Other isolated instances of disease associated with *P. multocida* are meningitis, encephalitis of calves and yearling cattle, manifested by muscle tremor, opisthotonos, rotation of the eyeballs, collapse, coma and death within a few hours; and lymphadenitis in lambs, which show enlargement of the submandibular, cranial, cervical, and prescapular lymph nodes. An epidemic of meningoencephalitis in horses, donkeys, and mules has been reported from Mexico. The causative agent was *Mannheimia haemolytica*. Clinical findings included incoordination, paralysis of the tongue, tremor, and blindness. Death occurred 1–7 days after the commencement of the illness. There is also a report of a fatal septicemia in horses and donkeys in India in which *P. multocida* appeared to be implicated as a causative agent. *M. haemolytica* is one of several bacterial pathogens causing otitis externa in cattle.

*Pasteurella* (Yersinia) *pseudotuberculosis* is a common cause of epizootic disease in birds and rodents and occasionally causes disease in domestic animals. It is described under a separate heading in this chapter. The literature of the molecular biology of *P. multocida* has been reviewed.

**REFERENCES**

**PASTEURELLOSIS**

The nomenclature of the diseases associated with infections with *Pasteurella* spp. in farm animals has been indefinite and confusing. A suggested nomenclature is set out below, which is based on the clinical findings and on the bacteria that are commonly associated with each entity.

- **Septicemic *pasteurellosis* of cattle** (hemorrhagic septicemia or barbone), commonly associated with infection by *P. multocida* type 1 or B, is the classical disease of southern Asia characterized by a peracute septicemia and a high mortality rate. Antibodies against *P. multocida* capsular types B and E were demonstrated in a high percentage of serum samples from a group of domestic feeder calves in the USA. Since capsular E organisms have been isolated only in Africa and there is only one report of capsular B isolation from cattle in the USA, these organisms were not considered to be the pathogenic organisms associated with *M. haemolytica*. There is a lack of multifocal coagulation necrosis in pneumonia associated with *P. multocida*.

- **Pasteurellosis of pigs, sheep, and goats**. In pigs this is usually associated with infection by *P. multocida* and is mainly pneumonia in form. Pasteurellosis of sheep and goats is usually associated with infection by *M. haemolytica* and, although it is often pneumonic in form, a septic form of the disease is not unusual, especially in lambs.

There are a number of immunologically distinct types of the common causative organism, *P. multocida*. These have been classified as types 1 (or B), 2 (or A), 3 (or C), and 4 (or D) and there is a loose relationship between the serotype and the host species. There is also some relationship between the serotype and the disease produced. Septicemic *pasteurellosis* is caused only by type 1 and, as this type does not occur in the UK and is uncommon in North America, it is not surprising to find that this form of the disease does not occur there.

The position with *M. haemolytica* is more obscure but preliminary work suggests that a number of serotypes occur and that there may be biological differences in virulence between them.

**REVIEW LITERATURE**

**SEPTICEMIC PASTEURELLOSIS OF CATTLE (HEMORRHAGIC SEPTICEMIA, BARBONE)**

**ETIOLOGY**

Hemorrhagic septicemia is associated with two specific serotypes of *P. multocida*. The Asian serotype is designated B2, 5 and the African serotype is E2 by the Carter–Heddestone system, corresponding to 6B and 6E by the Namioa–Garten system. The electrophoretic profiles of *P. multocida* isolates from animals with hemorrhagic septicemia can be placed in two distinct groups on the basis of their country of origin. Antibodies against *P. multocida* capsular types B and E were demonstrated in a high percentage of serum samples from a group of domestic feeder calves in the USA. Since capsular E organisms have been isolated only in Africa and there is only one report of capsular B isolation from cattle in the USA, these organisms were not considered to be the pathogenic organisms associated with *M. haemolytica*. There is a lack of multifocal coagulation necrosis in pneumonia associated with *P. multocida*.

- **Pasteurellosis of pigs, sheep, and goats**. In pigs this is usually associated with infection by *P. multocida* and is mainly pneumonia in form. Pasteurellosis of sheep and goats is usually associated with infection by *M. haemolytica* and, although it is often pneumonic in form, a septic form of the disease is not unusual, especially in lambs.
likely sources of the antigenic stimulation that provoked production of these antibodies.

Epidemiology
Hemorrhagic septicemia occurs in cattle, yaks, camels, and water buffalo and, to a much smaller extent, pigs and horses. It is considered economically important in southern Europe, Russia, Africa, the Near East, Middle East, South Africa, India, and southern and south-east Asia, including Indonesia, Malaysia, Thailand, and the Philippines, where it causes heavy death losses, particularly in low-lying areas and when the animals are exposed to wet, chilly weather or exhausted by heavy work. It is also recorded in bison and cattle in the USA and the causative bacterium and its endotoxin have been used to produce the disease experimentally. Animals of all ages are susceptible but the most susceptible age group is 6 months to 2 years of age. There is no difference in susceptibility between breeds. The incidence of disease is reduced significantly in areas where the vaccine is used. Both morbidity and case-fatality rates vary between 50% and 100%, and animals that recover require a long convalescence. Morbidity will depend on the immune status of the herd, either acquired naturally or induced by vaccination. The greater the percentage of immune to nonimmune animals, the lower will be the morbidity. In endemic areas, adult animals develop a naturally acquired immunity and large outbreaks no longer occur in these areas. The overall mean case fatality rate for buffaloes is nearly three times as high as in cattle.

Outbreaks of the disease are often associated with wet humid weather during the rainy season. During intervening periods the causative organism persists on the torsil and nasopharyngeal mucosa of carrier animals. Approximately 45% of healthy cattle in herds associated with the disease harbor the organism, in comparison to 3–5% in cattle from herds unassociated with the disease. Spread occurs by the ingestion of contaminated foodstuffs, the infection originating from clinically normal carriers or clinical cases, or possibly from ticks and biting insects. The saliva of affected animals contains large numbers of Pasteurella during the early stages of the disease. Although infection occurs by ingestion, the organism does not survive on pasture for more than 24 hours. The epidemiology of hemorrhagic septicemia in India has been described.

Pathogenesis
The portal of entry of infection is thought to be the tonsils. A fulminating septicaemia occurs, which is associated with the capsular material of the organism. The effects of the septicaemia are most severe in the respiratory tract, heart, and gastrointestinal tract. In cattle and buffalo there is rapid translocation of bacteria from the respiratory tract to the blood, liver, and spleen, suggesting that the bacteria are able to invade via the mucosal epithelial layers. Colostal immunity of calves from cows vaccinated against hemorrhagic septicemia peaks at 8–16 weeks of age and then declines.

Clinical Findings
The disease is an acute septicaemia and is clinically characterized by a sudden onset of fever (41–42°C, 106–107°F), profuse salivation, submucosal petechiation, severe depression and death in about 24 hours. On range lands, animals may be found dead without any clinical signs having been observed. Localization may occur in subcutaneous tissue, resulting in the development of warm, painful swellings about the throat, dewlap, brisket or perineum, and severe dyspnea may occur if the respiration is obstructed. In the later stages of an outbreak, some affected animals develop signs of pulmonary or alimentary involvement. Pasteurella may be isolated from the saliva and the bloodstream. The disease in pigs is identical with that in cattle.

Clinical Pathology
Culture and detection of bacteria
Laboratory diagnosis is by isolation and identification of the causative agent. The organism can be cultured from blood or a nasal swab from an animal within a few hours of death. Blood or a nasal swab during the clinical phase of the disease is not reliable because the septicaemia is a terminal event. From older carcasses, a long bone is used for culture from the bone marrow. Samples of blood are injected into mice, which will die in 24–36 hours. Smears made from the mouse blood or cultures of mouse blood will reveal the organisms.

Serology
A rapid ELISA is now available for the identification of the specific serotypes of *P. multocida* responsible for hemorrhagic septicemia.

Necropsy Findings
At necropsy, the gross findings are usually limited to generalized petechial hemorrhages, particularly under the serosa, and edema of the lungs and lymph nodes. Subcutaneous infiltrations of gelatinous fluid may be present and in a few animals there are lesions of early pneumonia and a hemorrhagic gastroenteritis. Varying degrees of lung involvement range from generalized congestion to patchy or extensive consolidation. Thickening of the interlobular septa may be prominent. Lymph nodes in the thoracic region are enlarged and hemorrhagic. Isolation of the causative bacteria is best attempted from heart, blood, and spleen.

Treatment
The disease occurs chiefly in areas where veterinary assistance is not readily available, and no detailed reports of the efficiency of various forms of treatment have been published. Oxytetracycline has been shown to be highly effective in pigs and sulfa drugs in cattle and the other treatments listed under pneumonic pasteurization of cattle should also be effective in this disease.

Control
The literature on hemorrhagic septicemic vaccines has been reviewed. Vaccines have been used for many years to protect cattle during the dangerous periods but the method was only moderately effective until the recent introduction of a stable vaccine composed of killed organisms in an adjuvant base containing paraffin and lanolin. This vaccine has been highly effective, especially when used prophylactically, although vaccination in the face of an outbreak may also reduce losses. Immunity after vaccination appears to be solid for at least 12 months and the only apparent disadvantage is the development of persistent subcutaneous swellings when the vaccine is improperly administered. Anaphylactic shock may occur in up to 1% of animals after the injection of some batches of vaccine. A potential refinement in the vaccine used is suggested by the finding that endotoxin-free capsular antigen of *P. multocida* types B and E is capable of immunizing cattle against challenge.

Plain broth bacterins, or alum-precipitated and aluminum hydroxide gel vaccines are administered twice a year since these vaccines offer immunity of 4–6 months. Many countries use oil adjuvant vaccine (OAV), which gives both a higher degree and a longer duration of immunity, up to 1 year. A double emulsion and a multiple emulsion vaccine of a thin viscosity have also been experimentally developed that provide immunity parallel to the OAV.

A live streptomycin-dependent mutant *P. multocida* vaccine provides good protection. A live vaccine containing *P. multocida* serotype B:3,4 isolated from a fallow deer in England has been developed and in preliminary field trials provided good protection. It protects cattle and buffaloes against B:2,5 challenge. Although the subcutaneous inoculation of the vaccine in buffalo calves under 5 months of age caused severe reactions and mortality, intranasal aerosol application is safe and has been used in immunizing cattle and buffaloes over 6 months of age. It has the advantages of protective action when lyophilized to a large-scale commercial product.

The vaccine has been shown to be safe and effective in the testing countries. The B:2 strain used in the vaccine was sensitive against B and B:2.

The immunity that results from the vaccine is directed against the capsular serotypes of *P. multocida* as well as to the strain.

The oral infection of a 1-year-old buffalo calf resulted in a marked increase in antibody titer 1 month later, while cows previously vaccinated against serotypematched strains did not respond.

The safety of this vaccine in cattle and buffaloes has been established in many countries.
apparent absence of anaphylactoid shock, protection for up to 1 year, easy preparation and a relatively small dose, and when lyophilized has prolonged viability. Freeze-drying would be necessary for large-scale production of the live vaccine.3

The Food and Agriculture Organization has reviewed development and use of the vaccine in Myanmar, has commended the intranasal use of live B3,4 vaccine as safe and potent, and has suggested that the technology be transferred to other countries.

The ara5 derivatives of the P. multocida B2 strains are being examined as possible antigens for a live attenuated vaccine.4 The safety and efficacy of these strains have been demonstrated in a mouse model of infection.6

The safety, efficacy, and duration of immunity of an improved oil-adjuvant vaccine containing inactivated cells of P. multocida serotype B:2,5 have been tested in young buffalo calves.7 Protection was satisfactory. To test for cross-protection against the heterologous serotypes E:2,5 and B:3,4, groups of mice were vaccinated once or left unvaccinated. Four weeks later, the vaccinated and control groups were challenged with a dilution series of the different challenge cultures. The vaccine appeared to induce protection against challenge with different strains of serotypes B:2,5 and E:2,5 but not against strains of serotype B:3,4.

The safety, efficacy and cross-protectivity of a live attenuated aerosol hemorrhagic septicaemia vaccine containing P. multocida serotype B:3,4 has been tested in young cattle and buffaloes in Myanmar, where more than 1.5 million animals were inoculated with the vaccine between 1989 and 1999.8 A recommended dose of 2 x 107 viable organisms was used for the efficacy test. The administration of 100 times the recommended dose to 50 cattle and 39 buffalo calves was innocuous. Three of these buffaloes were protected 7 months after they were vaccinated, and 12 months after they were vaccinated, three of four buffaloes were protected against a subcutaneous challenge with serotype B:2, which killed three of three unvaccinated buffaloes, while 12 months after they were vaccinated, eight of eight cattle survived a serotype B2 challenge that killed four of four unvaccinated controls. The vaccinated cattle had developed serum antibodies detectable by the passive mouse protection tests. Indirect hemagglutination tests on sera taken from cattle 10 days and 5 weeks after they were vaccinated showed high titers on antibodies. The serum of vaccinated cattle cross-protected passively immunized mice against infection with P. multocida serotypes E2, F:3,4, and A:3,4.

The intranasal aerosol vaccination is safe, even at very high dose levels, and does not induce anaphylactic shock even after repeated vaccinations. The freeze-dried live vaccine is stable for at least 3 years at room temperatures of 30–36°C, and thus a ‘cold chain’, which is impracticable for many hemorrhagic-septicemia-endemic areas, is not necessary for the storage and transport of the vaccine.

**BOVINE RESPIRATORY DISEASE: ACUTE UNDIFFERENTIATED BOVINE RESPIRATORY DISEASE**

**DEFINITION OF THE PROBLEM**

A major problem which large animal clinicians commonly encounter is a group of cattle that are affected with an acute respiratory disease of uncertain diagnosis.

Acute undifferentiated bovine respiratory disease (UBRD) is characterized clinically by dyspnea, coughing, nasal discharge, varying degrees of depression, inappetence to anorexia, a fever ranging from 40–41°C, evidence of pneumonia on auscultation of the lungs, and a variable response to treatment. Some unexpected deaths may have occurred as the initial indication of the problem.

In most cases, pneumonia is the cause of the disease but determining the etiology is the formidable diagnostic problem. If lesions typical of any of the common diseases of the respiratory tract of cattle can be recognized clinically, like those of infectious bovine rhinotracheitis, then on a clinical basis a specific diagnosis can be made.

The affected group may be recently weaned beef calves in a farm feedlot; weaned beef calves or yearlings that have recently arrived in a feedlot; cattle that have been in the feedlot for varying periods of time; young growing cattle on a clinical basis a specific diagnosis can be made.

In general, bovine respiratory disease accounts for 65–79% of the morbidity and 44–72% of mortality in feedlot cattle. In addition to direct costs associated with death loss and medical treatment, losses attributable to decreased growth performance associated with the incidence of bovine respiratory disease may also occur.

Cattle with detectable lung lesions at slaughter had a reduced (0.08 kg/d) growth rate compared with cattle without lesions. Also, 68% of cattle with lung lesions at slaughter were never treated for bovine respiratory disease, suggesting that current methods of diagnosing bovine respiratory disease based on visual appraisal by feedlot pen riders may not always effectively identify sick animals. In general, medical treatment is more effective the earlier in the process it can be initiated. The limitations of identifying clinically affected animals that need therapy was a major factor in the development of metaphylactic use of antimicrobials.

The primary goal of the clinician is to make the most accurate clinical diagnosis as rapidly as possible, based on the clinical and epidemiological findings that are identifiable on the farm, preferably when examining the animals on the first visit. Giving a prognosis and the formulation of rational and economic treatment that will minimize morbidity and mortality are the next goals. The outbreak may involve a herd of lactating dairy cows, and the selection of antimicrobials used can have a major impact on the length of time the milk from treated cows must be discarded. In any group situation, mass medication of each in-contact animal is a major consideration that will increase costs and must be balanced against the economic losses that might occur if all animals are not treated prophylactically. The clinical management of the outbreak, which includes treatment of the obvious cases and the prevention of new cases if possible, is dependent in part on the diagnosis. However, differentiation between the diseases based on clinical findings can be unreliable and it usually
necessary to begin antimicrobial therapy that will be effective against the bacterial pathogens most likely to be present. The specific cause may or may not be determined by laboratory examination or further clinical and epidemiological examination. Even after intensive clinical and laboratory investigation, the specific etiology will often not be determined and the clinician is left with a diagnosis of 'acute undifferentiated respiratory disease of cattle' or bovine respiratory disease.

The salient clinical and epidemiological findings of the diseases included in the complex of bovine respiratory disease are summarized in Table 18.5. The common diseases of the respiratory tract of cattle can be broadly divided into those affecting the lower respiratory tract and those affecting the upper respiratory tract. Diseases of the lungs associated with either viruses or bacteria alone or in combination are difficult to distinguish from each other on the basis of clinical findings alone. Thus in a group of cattle with pulmonary disease it may be difficult to distinguish between pneumonia, Haemophilus pleuropneumonia and the viral interstitial pneumonias with or without secondary bacterial infection. The presence of toxemia, which causes depression and anorexia in bacterial pneumonias, is a useful guide in categorizing the common diseases when making a differential diagnosis list. Cattle affected with uncomplicated viral diseases of the respiratory tract are usually not depressed and anorexic because bacterial toxemia is absent.

ETIOLOGY
The major etiological agents which cause or may be associated with acute UBRD include the following:
- Viruses
  - Bovine herpesvirus-1
  - Bovine respiratory syncytial virus
  - Parainfluenza-3 virus
  - Bovine virus diarrhea virus (BVDV)
  - Bovine respiratory syncytial virus (BRSV), and to Mycoplasma bovis and Mycoplasma dispar, within the first month after arrival. Seroconversion to these pathogens occurs both in animals that develop respiratory disease and those that remain normal within the same group, but the relative importance of each agent and their causative nature is controversial. Seroconversion to M. haemolytica cytotoxin, BRSV and BVDV were predictive of approximately 70% of all respiratory disease cases in Ontario feedlots.
- Calves arriving in Ontario feedlots with high serum antibody levels to Histophilus somni (formerly Haemophilus somnis) had less bovine respiratory disease than calves with lower levels.

Many respiratory pathogens that could cause disease present in both individuals and groups of feedlot cattle after they are mixed and during outbreaks of bovine respiratory disease. Which ones are most important and causing disease is a major question. It has been suggested that undifferentiated bovine respiratory disease in weaned beef calves entering a feedlot is not a contagious disease and that, while respiratory pathogens may be necessary causes of the disease, they are not sufficient causes. This suggests that groups of animals experiencing a high incidence of bovine respiratory disease have been highly stressed and that it may be more important to identify and prevent the environmental and managemental risk factors.

The relationships between bacterial and viral antibody titers and undifferentiated fever and mortality in recently weaned beef calves in western Canada were examined. Feedlot calves are commonly exposed to M. haemolytica, H. somni, bovine herpesvirus (BHV)-1, G-IV glycoprotein, BVDV, M. bovis, and Mycoplasma alakelseens in the early feeding period. Seroconversion to M. haemolytica antileukotoxin was associated with a decreased risk of undifferentiated fever. Higher antibody titer of BVDV antibody titers was associated with a decreased risk of undifferentiated fever. Higher survival H. somni antibody titer and increases in H. somni antibody titer after arrival were both associated with a decreased risk of undifferentiated fever. The odds of overall mortality (OR 5.09) and hemophilsis mortality (OR 11.31) in clinical cases were higher than in the controls. In summary, protective immunity to M. haemolytica antileukotoxin H. somni, BHV-1 G-IV glycoprotein, BVDV, and Mycoplasma spp. may be necessary to reduce the occurrence of undifferentiated fever.

Feedlot cattle commonly seroconvert to the viruses of infectious bovine rhinotracheitis (IBR), parainfluenza-3 virus (PI-3V), bovine virus diarrhea virus (BVDV), and bovine respiratory syncytial virus (BRSV), and to Mycoplasma bovis and Mycoplasma dispar, within the first month after arrival. Seroconversion to these pathogens occurs both in animals that develop respiratory disease and those that remain normal within the same group, but the relative importance of each agent and their causative nature is controversial. Seroconversion to M. haemolytica cytotoxin, BRSV and BVDV were predictive of approximately 70% of all respiratory disease cases in Ontario feedlots. Calves arriving in Ontario feedlots with high serum antibody levels to Histophilus somni (formerly Haemophilus somnis) had less bovine respiratory disease than calves with lower levels.

The odds of overall mortality (OR 5.09) and hemophilsis mortality (OR 11.31) in clinical cases were higher than in the controls. In summary, protective immunity to M. haemolytica antileukotoxin H. somni, BHV-1 G-IV glycoprotein, BVDV, and Mycoplasma spp. may be necessary to reduce the occurrence of undifferentiated fever.

The association between exposure to H. somni and M. haemolytica and the risk of acute UBRD was examined using serological evidence of exposure and a vaccine field trial. Vaccination with H. somni in combination with M. haemolytica and with M. haemolytica alone reduced the risk of UBRD. There was no association between serological evidence of concurrent exposure to M. haemolytica and UBRD occurrence. Treated animals tend to have lower titers to H. somni compared to untreated animals.

Chronic, antibiotic-resistant pneumonia, sometimes with polyarthrosis, occurs in feedlot cattle in western Canada. M. bovis, BVDV, and H. somni are commonly found in the tissues at necropsy. This coinfection suggests the possibility of synergism between the BVDV and M. bovis in the pneumonia with the arthritis syndrome.

BVDV has been identified as a contributor to respiratory disease in feedlot calves. On arrival in feedlots, 39% of animals were seropositive for BVDV, and those animals treated for UBRD had larger titers increases to the virus than non-treated animals. The virus has been demonstrated by experimental infections of the respiratory tract, isolation of the virus and/or identification of BVDV antigen in tissues and demonstration of active infection through seroconversion in groups of cattle with bovine respiratory disease. BVDV-1b strains have been associated with acute pneumonia in commingled calves that were not vaccinated with BVDV vaccines, and in which M. haemolytica and P. multocida were also commonly found in the pneumonia lesions. Experimental infection of seronegative and immunocompetent calves with BVDV type resulted in primary respiratory disease.

Bovine coronavirus (BCV) has been implicated as a cause of UBRD based largely on the isolation of the virus from the nasal cavities of cattle with respiratory disease. However, based on sero-epidemiology of BCV titers in feedlot cattle, although higher antibody titers to the virus were associated with a decreased subsequent risk of treatment for UBRD, there was no association between evidence of recent infection (titer increase) and the occurrence of UBRD. Other studies have shown that BCV infections are not associated with an increased risk of treatment for UBRD.

BCV is widespread in the cattle population and can be isolated from nasal swabs from cattle with bovine respiratory disease. The virus can be found in the feces and nasal swabs of recently arrived feedlot cattle and calves with and without clinical signs of bovine respiratory disease. Exposure to BCV prior to arrival in the feedlot is common, with 90% of animals...
Diseases associated with Pasteurella species

In commercial feedlots, where large numbers of clinically affected animals are processed daily, and time is an economically important factor, the clinical examination of affected animals may be cursory and limited to taking the rectal temperature of animals that have been identified as sick based on recognition of depression and the absence of clinical findings suggestive of disease of some body system other than the respiratory tract. In such instances, if depressed animals have a rectal temperature above a predetermined level of, for example, 40°C, they are considered to have bovine respiratory disease, if no other clinical findings are detectable that are referable to organ systems other than the respiratory system. In such cases, a diagnosis of acute undifferentiated fever of feedlot cattle has been suggested. In most cases, the thorax of these animals is not auscultated for evidence of pneumonia. As a result it is probable that the number of animals with respiratory disease is overestimated. Undoubtedly, some sick feedlot animals have a fever of undetermined origin unassociated with respiratory disease or any other inflammatory lesion. In a pen of recently arrived cattle in a feedlot, many animals that appear normal but have rectal temperatures above the critical temperature without any clinical evidence of bacterial infection that requires treatment. The elevated temperatures of these animals will return to within normal ranges within a few days.

The subjective clinical findings of distant examination that have been used by animal attendants in commercial feedlots to identify sick animals that need to be closely examined include: degree of ruminal fill (1, normal; 2, slightly gaunt; 3, moderately gaunt; 4, excessively gaunt), attitude (1, normal; 2, slight lethargy; 3, severe lethargy; 4, nonambulatory), ocular discharge (1, none; 2, slight; 3, moderate; 4, abundant), nasal discharge (1, none; 2, slight; 3, moderate; 4, abundant). The sounds heard on auscultation of the lungs at three sites along a line extending from the cranioventral to caudodorsal lung fields (1, normal; 2, slightly harsh; 3, moderately harsh; 4, severely harsh). The feeding and watering behavior of healthy and sick animals in a commercial feedlot has been examined using radio-frequency technology to record individual animal behaviors. Eating and drinking behaviors are associated with clinical signs of bovine respiratory disease but there is no obvious predictive association between signs of bovine respiratory disease in recently arrived weaned beef calves and eating and drinking behavior.

Calves that were sick had greater frequency and duration of drinking 4–5 days after arrival than calves that were not sick. Sick calves had significantly lower frequency and duration of eating 11–27 days after arrival but had greater frequency of eating 28–57 days after arrival than calves that were not sick. Calves at slaughter that had a higher percentage of lung tissue with lesions had lower frequency and duration of eating 11–27 days after arrival but had greater frequency and duration of eating 28–57 days after arrival. Agreement of calves being sick and having pulmonary lesions at slaughter was adequate. Agreement for calves being removed and having pulmonary lesions at slaughter was low. Experimentally, the electronic lesions at slaughter was adequate.

Pneumonic pasteurellosis is most common in recently arrived feedlot calves. In calves 3–5 weeks after arrival in the feedlot, H. somni pleuro pneumonia may be more likely. Acute interstitial pneumonia (pasteurella induced) is the most likely diagnosis when confronted with an outbreak of acute respiratory disease in mature beef cattle that have been moved from a summer pasture to a fall autumn pasture within the last 4–10 days. Acute pulmonary disease in a few head of feedlot animals several weeks or months after arrival in the lot is probably an acute interstitial pneumonia, which may be associated with 3-methylindole (3MI) metabolites.

Risk factors

The risk factors that have been identified in outbreaks of respiratory disease in feedlot cattle include the purchase of cattle from auction markets, whereby cattle arrive at the feedlot over an extended period of time, and mixing of cattle from many different sources. An epidemiological study of fatal fibrinous pneumonia in auction-market-derived feedlot calves in western Canada revealed that peak mortality occurred approximately 16 days after arrival at the feedlot. The risk of fatal fibrinous pneumonia was consistently greater for calves entering the feedlot in November, shortly after the auction sales had peaked, when the feedlot was reaching capacity. Mixing of calves from different farms was considerable, with a median of two calves per farm on truckloads arriving at the feedlot. Increased mixing at the auction markets was associated with increased fatal disease risk. The distance calves were transported by truck from the auction markets to the feedlot was not associated with fatal disease risk. When the incidence of fatal fibrinous pneumonia was high, the disease clustered within truckloads or pens. Risk factors positively associated with disease clustering included increased mixing of calves from different farms at the auction markets, month of purchase, number of calves passing through the auction markets, and weather conditions at arrival. Transportation of feedlot calves increases serum concentration of oxidative stress biomarkers, which are related to episodes of bovine respiratory disease. Transportation significantly decreases serum total antioxidant capacity and increases malondialdehyde concentrations in steer calves. It is proposed that stressors such as marketing (through an auction barn) and transportation to the feedlot precipitate oxidative stress, which reduces the antioxidant defense capacity and increases total body lipid peroxidation, resulting in increased susceptibility to bovine respiratory disease. These biomarkers may be useful to measure the oxidative stress of transported cattle. There is some experimental evidence that acridogenic diets and ketoacidosis may affect lymphocyte function, which may affect vaccine efficacy.

The literature on how the adequacy of diets of recently arrived feedlot cattle may affect their health and immunity has been reviewed. Diets for newly arrived stressed beef cattle must be formulated to compensate for decreased feed intake and known nutrient deficiencies.

The literature on the risk factors for bovine respiratory disease in dairy heifers and the effect of the disease on productivity has been reviewed with relevance to commercial dairy farming in the Netherlands. Bovine respiratory disease in dairy heifers increases the risk of mortality directly after the disease episode by up to six times, reduces growth during the first 6 months of life by up to 10 kg, and increases the likelihood of dystocia after first calving. Both herd size and other diseases in dairy heifers are clearly associated with the risk of bovine respiratory disease. Season and colostrum feeding are important. The most important risk factors for mild and severe pneumonia in dairy calves aged birth to 3 months were inadequate air circulation and the purchase of cattle.

An epidemic of acute respiratory disease associated with BRSV occurred during the winter and spring of 1995 in Norway. Data from 431 cattle herds were collected. The risk of acute respiratory disease occurring in cattle was related to herd size and type of production and an expressed interaction between these two variables. The risk of a herd outbreak in a mixed herd of 20 animals was estimated to be 1.7 times greater than in a dairy herd, and 3.3 times greater than in a beef herd of 20 animals.
comparable size. On increasing herd size to 50 animals, the risk increased 1.3-fold for a mixed herd, 3.3-fold for a dairy herd, and 2.1-fold for a beef herd, compared to a risk for a corresponding type of herd of 20 animals. The disease spread initially from one location to another during the first 6–9 weeks; the rate of transmission between neighboring farms seemed to be higher than for the other districts included in the study. It was hypothesized that one common source of infection was involved in the outbreak and the case herds were clustered in time as well as spatially. The average daily milk loss was estimated to be 0.70 kg per cow for 7 days after a herd outbreak compared with the period one week before.98

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The clinician is limited in most situations to correlating clinical, epidemiological, and necropsy findings in making a diagnosis. Diagnostic laboratories may not be readily available and their resources for microbiological and serological investigations may be much less than is needed for an accurate determination of causes. In the past, investigations of outbreaks of bovine respiratory disease have been incomplete and the interpretation of the findings almost impossible because one or more pieces of information were missing.

A number of important factors contribute to the difficulty of unraveling the etiologies in field outbreaks of respiratory disease. A review of the literature on the morbidity and mortality rates and disease occurrence in North American feedlots found differences in the definition of the terms used that makes the reports difficult to compare.99 In addition, the case definition or the clinical diagnosis is invariably inadequately defined. In feedlots, the morbidity rate will range from 15–45% of cattle within 3 weeks after arrival and the population mortality rate varies from 1–5%. Respiratory diseases account for about 75% of the diseases. Three important items are to be considered:

- Case definitions should be clearly stated.
- The population at risk should be precisely measured.
- The period of observation must be stated.

A systematic method of data collection from the customized records of large feedlots has been developed and validated for use in the National Animal Health Monitoring System. The current collection of data from large feedlots provides an acceptable level of sensitivity and specificity for the program but it is important that the veterinarian makes regular clinical observations to validate the data.

The course of the disease, especially when animals have been treated, alters the gross and microscopic appearance of tissues and the microbiological (bacteriological, virological) and serological findings so that the animal’s status is impossible to determine.

CLINICAL PATHOLOGY

Bacterial culture and antimicrobial sensitivity

Nasal swabs taken from clinical cases before treatment often yield a pure culture of pasteurellas but _M. haemolytica_ biotype A serotype 1 is the most common isolate obtained from cattle with acute pulmonary Pasteurellosis. The same serotype can usually be isolated from in-contact and apparently healthy calves. The antimicrobial sensitivity of the pasteurellas isolated can be done, but interpretation of the results is often difficult because it is not known whether the isolates from nasal swabs represent the organisms causing the lesions. Significant differences may exist between the antimicrobial sensitivities of isolates from nasopharyngeal swabs and those from the lung tissues. Thus it is not possible to interpret routine culturing using the traditional Pasteurella Isolation Procedure. The subcommittee found that MIC breakpoints and zone-diameter interpretative criteria that best fit the definition of intermediate susceptibility are needed for an accurate determination of causes.

The breakpoints for oxytetracycline and florfenicol, spectromycin, and tilmicosin are adapted from human studies.41

Virus isolation or detection

Nasal swabs may be submitted for isolation or detection of viruses such as BHV-1, BRSV, bovine coronavirus.

Serology

Serum samples may be submitted for determination of the levels of specific antibody to suspected viral causes of the bovine respiratory disease. Paired acute and convalescent serum samples from both affected and normal animals in the herd are desirable. In a group of animals in a feedlot, or dairy or beef cattle herd, serology for a specific antigen should be followed over a period of time to determine seroconversion and its relationship to occurrence or absence of clinical disease.

Hematology

Plasma fibrinogen concentrations are elevated, paralleling the increase in body temperature, and are a more reliable indication of the presence of the lesion than clinical assessment. Young cattle with clinical signs of acute respiratory disease, a fibrinogen concentration greater than 0.7 g/dL, and a temperature greater than 40°C (104°F) are likely to have pneumatic Pasteurellosis. Leukocyte counts are of little value, as a leukocytosis and neutropenia occur in some animals but in others there may be a neutropenia...
or no significant change. Acute phase proteins are increased within 24 hours following experimental intratracheal inoculation of *M. haemolytica* into calves. The availability of a rapid test for acute-phase proteins could assist in the field diagnosis of the disease and its possible differentiation from similar diseases.

**NECROPSY FINDINGS**

Necropsies should be done on all animals that die with the disease. In feedlots this is a means of obtaining daily information on the occurrence of specific diseases and on the efficacy of the animal health management program. The most common pathological finding is fibrinous pneumonia and coagulation necrosis, with varying degrees of the common complications such as pleuritis and pulmonary abscesses. One of the major problems in the diagnosis of feedlot pneumonia has been to assess the age of the lesions. Determining the age of a bacterial pneumonia with some accuracy would help the health management to assess whether or not the pneumonia was already present in the animal on arrival or whether a treatment failure resulted from late detection or from inadequate drug therapy. An attempt to age the lesions of bacterial pneumonia of feedlot cattle indicated that the degree and extent of necrosis and fibrosis offers the best opportunity to age the pneumonia. In acute interstitial pneumonia, the lungs are diffusely red-tan, enlarged, and do not collapse. All lobes are rubbery, wet, and heavy. Emphysema is present mainly in the diaphragmatic lobes and there is white froth in the trachea. In fibrinous pleuritis there are thick sheets of fibrin over the visceral and parietal pleura. The thorax contains fibrin and straw-colored fluid. In caudal vena cava thrombosis, the lungs contain pulmonary arterial aneurysms and abscesses. Blood clots are present in the airways and the liver has an abscess near the vena cava that contains a thrombus.

Tissue samples are submitted for histopathology and bacteriological and virological examination depending on the specific disease suspected. However, the length of time usually required to do the diagnostic work and interpret the results means that the procedure is expensive and to an extent inconclusive because the results are available only when the outbreak is over.

A method has been described of recording pulmonary lesions of beef calves at slaughter and the association of lesions with average daily gain.

Computer imaging technology can be employed to facilitate the capture of feedlot necropsy data. A digital camera is used to capture necropsy findings and the images are electronically transferred to a central reference laboratory for veterinary interpretation and diagnosis.

**Interpretation of results of clinical pathology and necropsy findings**

A large body of information has been generated on the microbiology, and more recently molecular microbiology, of specific pathogens associated with bovine respiratory disease but only a small amount is applicable clinically. Insufficient effort has been directed towards integrating the information and applying it to the effective control of respiratory disease on the farm. Ideally, investigations of outbreaks of bovine respiratory disease should consist of in-depth examinations of a representative sample of the affected group and normal in-contact animals using a multidisciplinary approach involving clinical, epidemiological, and laboratory investigation. These procedures, especially those requiring detailed virological and serological examinations, are expensive and in the light of the economic status of cattle industries not likely to be lightly borne. But it will only be when such a multidisciplinary approach is brought to bear on bovine respiratory disease that we will improve our position with respect to knowing what actually occurs in outbreaks of the disease. Of paramount importance is the identification of risk factors, which, if valid, gives the clinician a powerful clinical tool for the clinical management and control of respiratory disease in cattle. Of even greater importance is the necessity for the clinician to visit the farm and conduct those clinical and epidemiological investigations that are necessary to solve the problem and to monitor the problem and the herd until recovery occurs.

**TREATMENT**

The principles of the clinical management of outbreaks of acute undifferentiated bovine respiratory diseases are:

- The clinician must visit the farm and do the clinical and epidemiological investigations necessary to solve the problem, to assist the owner or the animal attendants with the clinical management of the disease, and to monitor the problem and the herd until recovery occurs. Simply dispensing antimicrobials to the owner without clinical examination of the animals is inadequate and contradicts the intention of the veterinarian–client relationship. The veterinarian is professionally obliged to provide explicit instructions about medication of affected animals and the drug withdrawal requirements, and to keep adequate records of affected animals, treatments given and the results of laboratory examinations. A final report should be prepared by the veterinarian and sent to the owner.
- Unless otherwise determined, when toxemia and fever are present it is assumed that a primary bacterial pneumonia is present or, if a viral interstitial pneumonia is suspected, then a secondary bacterial pneumonia may occur. Therefore, antimicrobial therapy is of prime importance.
- New cases must be identified as soon as possible. This will require increased surveillance of the group to detect affected animals as soon as clinical abnormalities such as depression, nasal discharge, and dyspnea are noticeable.
- New cases must be treated as soon as they are detected. Each treated animal should be suitably identified and a record kept of the initial body temperature and the treatment administered. If the outbreak is due to a bacterium, failure to respond favorably to antimicrobial therapy or relapse that occurs a few days after an initial apparent recovery is usually due to late treatment. Delaying treatment until 48 hours after an experimental aerosol injection of *M. haemolytica* can prolong the course of the disease and increase mortality.
- Any of the common antimicrobials must be administered parenterally daily for at least 3 days.
- Oxytetracycline at 10 mg/kg BW intramuscularly, procaine penicillin G at 30,000-45,000 IU/kg BW intramuscularly, or trimethoprim-sulfadiazine at 3 mL/45 kg BW intramuscularly are effective when given early in the course of the disease.
- Tilmicosin at a dose of 10 mg/kg BW subcutaneously is also effective.
- Florfenicol at 20 mg/kg BW intramuscularly and repeated 48 h later is also highly effective. Florfenicol and tilmicosin are comparable for treatment of undifferentiated bovine respiratory disease in western Canada.
- Florfenicol is superior to tilmicosin for the treatment of undifferentiated fever in feedlot calves that have previously received metaphylactic tilmicosin upon arrival in the feedlot in western Canada.
- Enrofloxacin at 2.5-5.0 mg/kg BW intramuscularly daily for 3-5 days or a single dose of 7.5-12.5 mg/kg BW is effective for the treatment of bovine respiratory disease.

In lactating dairy cows, antimicrobials with the shortest milk withdrawal times commensurate with effectiveness should be administered.
due to respiratory disease during the first 2 weeks on feed and for the entire feeding period by 15–19% and the mortality rate from fatal fibrinous pneumonia by 67–84%. Meta-analysis of field trials of antimicrobial mass medication for prophylaxis of bovine respiratory disease in feedlot cattle indicated that prophylactic parenteral mass medication of calves with long-acting oxytetracycline or tilmicosin on arrival at the feedlot would reduce morbidity rates. **CONTROL**

The control of outbreaks of acute bovine respiratory disease will depend on mass medication or metaphylaxis, minimizing the effects of the risk factors and enhancing immunity by the judicious use of vaccines. **Mass medication or metaphylaxis**

The parenteral administration of antimicrobials to each animal as a form of mass medication may assist in the reduction of morbidity and mortality rates due to respiratory disease. The use of long-acting oxytetracycline at a dose of 20 mg/kg BW intramuscularly to feedlot cattle on arrival significantly reduced morbidity and mortality rates. The combined use of long-acting oxytetracycline at a dose of 20 mg/kg BW intramuscularly on arrival followed by the oral administration of 25 g of sustained-release sulfadimethoxine on day 3 resulted in a 90% reduction in treatment days per calf purchased. Tilmicosin, given at a dose of 10 mg/kg body weight subcutaneously to calves on arrival in the feedlot or 72 hours later, can significantly reduce the morbidity rate due to respiratory disease and improve the rate of gain.46

A formulation of long-acting oxytetracycline (300 mg/mL) at a dose of 30 mg/kg BW intramuscularly is superior to the standard formulation of long-acting oxytetracycline (200 mg/mL) given at 20 mg/kg BW.47 The 300 mg/mL preparation of oxytetracycline is also more cost-effective than tilmicosin.48

Mass medication of cattle on entry into feedlots in Australia with tilmicosin at 10 mg/kg BW grew 0.08 kg/d faster than cattle medicated with oxytetracycline at 20 mg/kg BW and nonmedicated cattle.49 There was no significant difference in growth rate between oxytetracycline-mediated cattle and those not medicated on entry into the feedlot. Cattle medicated with tilmicosin had fewer treatments for all illnesses compared with cattle not given an antibiotic on entry to the feedlot and compared with cattle mass-mediated with oxytetracycline. Tilmicosin induces apoptosis in pulmonary neutrophils, leading to a reduction in leukotriene B4 synthesis, thereby reducing further amplification of the inflammatory injury of bovine respiratory disease. Premedication of cattle with tilmicosin are not more effective than mass medication on arrival.50

The mass medication of feed supplies of newly arrived feedlot cattle has been investigated as a method of reducing the morbidity and mortality due to respiratory disease. The provision of chlortetracycline in the feed at a rate of 1, 2, or 4 g per head daily during the 2-week period after arrival reduced the number of calves that required treatment for respiratory disease.

**Management of risk factors**

As a general outline for the control of bovine respiratory disease the following factors are considered as contributing to disease and their effects must be minimized with suitable management and disease prevention techniques.

- Young growing cattle are more susceptible than mature cattle because of a lack of sufficient immunity. The mixing of young cattle of different origins requires increased surveillance to detect evidence of disease. Vaccination of calves at strategic times may be necessary.
- Cattle purchased from various sources and mingled in a feedlot are more likely to develop bovine respiratory disease than cattle that have originated from one source. Some cattle will be highly susceptible and others relatively resistant because of differences in nasal flora and immunological, genetic, and nutritional backgrounds. A high level of management and constant surveillance are necessary to recognize, isolate, and treat clinical cases early in order to minimize morbidity and case mortality.
- Rapid fluctuations in environmental temperatures and relative humidity, not only during the fall and winter months but also during warm seasons, will commonly precede outbreaks of respiratory diseases.
Every practical and economical management technique must be used to provide as much comfort as possible and to avoid overcrowding. Inadequate ventilation is a major predisposing cause of respiratory disease of cattle raised indoors. This is of major importance in dairy herds during the winter months in temperate climates.

- The weaning of beef calves during inclement weather may exacerbate the stress of weaning and commonly results in an outbreak of respiratory disease.
- The stress associated with the marketing of cattle is a major factor. The movement of cattle through saleyards—where they may be overcrowded, mixed with cattle of many different origins, temporarily deprived of adequate feed and water, handled roughly while being sorted, weighed, tagged, blood sampled, vaccinated or injected with antibiotics and/or vitamins and then loaded on to uncomfortable vehicles and transported long distances without adequate rest stops—is stressful. The practice of preconditioning cattle before they enter the feedlot must continue to be examined to determine which aspects are most profitable.

Presale vaccination programs are designed to establish an effective immune response to common respiratory tract pathogens well in advance of any natural exposure that may occur while calves travel through the auction market or after they arrive in the feedlot. These programs usually require calves to be castrated, dehorned, and vaccinated against IBRV, PI-3V, BRSV, and BVDV. Some programs also require vaccination against *H. somni* and *M. haemolytica*. Presale conditioning programs involve these procedures but also include weaning and nutritional components. Most such conditioning programs require calves to be weaned and adjusted to a roughage and concentrate diet for at least 30 days prior to sale.

Presale vaccination and conditioning programs have increased and decreased in popularity since their introduction in the 1970s. Producers tend to be reluctant to adopt these practices, because there is no assurance they will be rewarded, in terms of price premiums, for their efforts. However, the establishment of special auctions in Ontario that feature large numbers of vaccinated or conditioned calves resulted in an increased interest in these management practices. Producers selling lots of vaccinated or conditioned feeder calves through special auctions received a premium sale price compared with lots of feeder calves sold through conventional auctions. Vaccinated and conditioned calves were less likely to receive treatment for bovine respiratory disease during the first 28 days in the feedlot; but there was no difference in mortality. Calves that received antimicrobials on arrival at the feedlot had a reduced risk of treatment for bovine respiratory disease compared with calves that did not.

**Vaccines**

While vaccines are available for the control of acute respiratory disease associated with IBRV, PI-3V, and *Pasteurella* spp., there are almost no reports available of their efficacy determined under scientifically designed field trials. Based on current immunological technology, efficacious vaccines are considered to be feasible. The vaccines have been evaluated by experimental challenge of vaccinated animals with specific pathogens in a laboratory environment. However, there is little scientific evidence available that the vaccines are protective against acute UBRD as it occurs in the 'real world' situation. Preshipment vaccination of beef calves 3 weeks prior to weaning with vaccines containing IBRV, PI-3V, *Pasteurella* spp., and *H. somni* did not reduce the incidence of UBRD compared to those unvaccinated.

**Pasteurella bacterins and respiratory viral vaccines** have been used extensively in an attempt to control bovine respiratory disease. Many veterinarians and feedlot owners maintain that vaccination against respiratory disease is an essential component in their disease prevention programs, both to prevent specific disease of the respiratory tract such as clinical infectious bovine rhinotracheitis and to reduce losses due to respiratory disease in the first few weeks after arrival. However, a review of the literature on the efficacy of the vaccines available for the control of bovine respiratory disease concluded that there are few documented field trials to evaluate the efficacy of the vaccine against naturally occurring disease in the field with vaccinated animals and unvaccinated animals as concurrent controls. In most cases the vaccines were approved for sale on the basis of tests for safety in animals, and the potency measured by a serological response to the vaccine or experimental challenge in animals under laboratory conditions.

The information available about the commercial vaccines currently used in Canada for protection against bovine respiratory disease has been reviewed. Various combination vaccines containing modified live virus, killed virus, bacterins, and/or bacterial culture supernatants/surface extracts are available.

**Efficacy of vaccines**

Meaningful field trials to evaluate vaccines for the control of bovine respiratory disease are difficult to achieve. The case definition of what is a 'case of respiratory disease' varies, depending on the place of origin. The information available about the commercial vaccines currently used in Canada for protection against bovine respiratory disease has been reviewed. Various combination vaccines containing modified live virus, killed virus, bacterins, and/or bacterial culture supernatants/surface extracts are available.

In North America a large number of bacterial and viral vaccines are available for the control of bovine respiratory disease. There are single antigen or multiple antigen vaccines, modified live virus or inactivated virus vaccines containing one or more of the following antigens: *M. haemolytica*, *H. somni*, IBRV, PI-3V, BRSV, and BVDV. There are many multiple antigen vaccines containing combinations of the respiratory viruses, BVDV, *H. somni*, and *M. haemolytica*. In western Canada it is more cost-effective to vaccinate auction-market-derived, fall-placed feedlot calves with a multivalent viral vaccine containing IBRV, PI-3, BVD, and BRS viruses than a single univalent viral vaccine containing IBRV only.

**Selection of vaccines**

The selection of which vaccine to recommend for the control of UBRD in feedlot cattle is currently not possible based on the efficacy information which is available to the veterinarian. The vaccines are used widely and many anecdotal claims for their effectiveness are made but there is little scientific evidence based on properly designed field trials that the vaccines are effective and economical in reducing the incidence or the consequences of respiratory disease such as suboptimal weight gain. The major problem has been that vaccine manufacturers have not conducted a sufficient number of well-designed field trials to evaluate the efficacy of the vaccine against naturally occurring disease in the feedlot cattle is currently not possible. There is little scientific evidence based on properly designed field trials that the vaccines are effective and economical in reducing the incidence or the consequences of respiratory disease such as suboptimal weight gain.

Field trials to evaluate vaccines for the control of bovine respiratory disease are difficult to achieve. The case definition of what is a 'case of respiratory disease' varies, depending on the place of origin. The information available about the commercial vaccines currently used in Canada for protection against bovine respiratory disease has been reviewed. Various combination vaccines containing modified live virus, killed virus, bacterins, and/or bacterial culture supernatants/surface extracts are available.
respiratory disease in vaccines and controls it is difficult to evaluate one of the vaccines or the components of a multiple antigen vaccine unless large numbers of animals are used. Another problem is the difficulty of having the controls and the vaccines experience approximately the same risk of being affected with respiratory disease.

Field trials for bovine respiratory disease vaccines are often unsatisfactory because of inadequate planning, unsatisfactory experimental design and lack of monitoring. A check list of key elements to consider when assessing the clinical research published for a particular vaccine has been suggested. The following items should be considered:

- Has the vaccine been laboratory and field tested in randomized controlled field trials? If so, how many trials, and, in each case:
  - Were the control groups concurrent or historical?
  - How were the trial animals challenged?
  - Was the measure of outcome meaningful?
  - Were the biology and epidemiology of the disease considered?
  - Was the vaccine assigned randomly?
  - Were blinding techniques used to reduce bias?
  - What other potentially important biases are evident?
  - How likely is it that the result was a chance finding?
  - What are the differences between the trial animals and animals in your practice? Are these differences important with respect to the vaccine?

A field trial was conducted to compare the serological responses in weaned beef calves 6–8 months of age vaccinated against IBRV, PI-3V, BRSV, and BVDV. There were significant differences in serological responses among the various commercial vaccines. Antibody titers to IBRV were higher in calves vaccinated with modified-live virus IBRV vaccines than when the inactivated vaccine was used. Following double vaccination with modified-live virus IBRV and PI-3V vaccines, seroconversion rates and antibody titers were higher in calves vaccinated intramuscularly than those vaccinated by the intranasal route. It is not known if these differences reflect differences in vaccine efficacy under field conditions. The effect of using multiple antigens in the same vaccine on the serological responses is not clear. In some cases, vaccines containing the BRSV antigen resulted in lower titers to BVDV and PI-3V than vaccines that did not contain the BRSV.

The following comments on the use of vaccines as an aid in the control of acute undifferentiated respiratory disease in feedlot cattle are based on the current information available.

Pasteurella vaccines
Because fibrinous pneumonia associated with *M. haemolytica* is the most common lesion associated with bovine respiratory disease in feedlot cattle, much of the emphasis has been on the development of effective vaccines for bovine pneumonic pasteurellosis. Based on the immunological and microbiological observations of both naturally occurring and experimentally induced pneumonic pasteurellosis it appears that effective artificial immunization of cattle is possible. High levels of naturally acquired antibody to *M. haemolytica* have been associated with protection against the disease.

Calves that recover from experimentally induced pneumonic pasteurellosis possess increased resistance to subsequent experimental challenge. Calves that were naturally exposed to *M. haemolytica* or exposed by vaccination subcutaneously or intradermally to the live organisms developed some resistance to experimental challenge and developed antibodies to all surface antigens and cytotoxin. Resistance to experimental challenge with the organism correlated directly with serum cytotoxin neutralizing titer. This supports the hypothesis that protection against experimental challenge with *M. haemolytica* may require an immune response to cytotoxin. This is supported by the observation that cattle that died from fibrinous pneumonia due to *M. haemolytica* had lower cytotoxin neutralizing activity in their sera than cattle from the same group that died from other causes.

Antibodies to leukotoxin and certain bacterial surface components appear to be important for resistance to disease. The basis of a recently introduced pasteurella vaccine is that vaccination of calves with a leukotoxic culture supernatant from pathogenic *M. haemolytica* provided some protection against experimental challenge with the organism. The vaccine has been evaluated in field trials in feedlots in Canada with variable results. In one trial, the vaccine was used on arrival in fall-calves and reduced the pull rate by 4%, the first relapse rate by 11.9% and the second relapse rate by 18.7%. There was an 8.2% decrease in the mean number of treatment days. Overall mortality was decreased by 49% and mortality rate due to fibrinous pneumonia was reduced by 50%. It appeared that vaccinated animals also responded more favorably than non-vaccinated animals. Vaccination of recently shipped nonpreconditioned calves with the vaccine in Ontario resulted in a slight decrease in morbidity, slight improvement in response rates and perhaps an important reduction in relapse rates. When the vaccine was combined with an intramuscular modified-live IBR/PI-3 virus vaccine, the morbidity rate was increased, the response rate was decreased and the mortality rate was increased in some groups. It appears that the use of modified-live virus vaccines in recently arrived calves is contraindicated; this is consistent with earlier observations in the Bruce County Project, where fall-placed calves were vaccinated on arrival with a modified-live virus vaccine.

The *Pasteurella* vaccine has also been evaluated in a field trial that compared its efficacy in calves vaccinated at the ranch 3 weeks prior to shipping to the feedlot, vaccination of ranch calves on arrival in the feedlot, and auction mart calves assigned to either receive or not receive the vaccine on arrival at the feedlot. The vaccine did not effect a change in morbidity rates or weight gain. Total mortality rates were increased significantly, and mortality rates from respiratory disease tended to increase in ranch calves that were vaccinated at the ranch. In auction-mart-derived calves, the relapse rates were significantly lower in vaccinated calves. The source of calves was a major factor affecting the incidence and/or effects of bovine respiratory disease. Calves moved directly from the ranches to feedlots, regardless of vaccination status, had lower morbidity and mortality, and better weight gains, than calves purchased from auction marts.

*Histophilus somni* (formerly *Haemophilus somni*) vaccine
A *H. somni* bacterin evaluated in a large number of feedlot cattle had no effect on the overall crude mortality rate; however, vaccination appeared to reduce the incidence rate of fatal disease and the mortality rate during the first 2 months in the feedlot, when risk of fatal disease onset was highest. The incidence of fatal disease onset was highest during the first week after arrival, which suggests that inclusion of a *H. somni* bacterin in a cow-calf preimmunization program might reduce the proportion of disease that occurs during the first week in the feedlot. Crude mortality and incidence of fatal disease onset during the second week were reduced significantly in the vaccinated steers. It was concluded that about 17% of fatal respiratory disease in the unvaccinated...
steiners could have been prevented by vaccination with the *H. somni* bacterium. Fibrous pneumonia was the most common pathological diagnosis. Vaccinating calves twice with a killed whole-cell *H. somni* bacterin reduced the clinical and pathological effects of experimentally induced *H. somni* pneumonia.

**Viral vaccines**

Because prior infection of the respiratory tract with either IBRV or PI-3V may predispose to pneumonic pasteurellosis, the vaccination of beef calves 2–3 weeks before weaning and feedlot cattle 2 weeks before shipment to a feedlot has been recommended as part of a preconditioning program. The results are variable, but vaccination of calves at 3–6 months of age with an intranasal modified-live IBR and PI-3V virus vaccine has provided protection against experimental pneumonic pasteurellosis induced by aerosol challenge with IBR followed 4 days later by an aerosol of *M. haemolytica*. It is important to vaccinate the calves at least 2 weeks before they are weaned, stressed, or transported to a feedlot.

A modified-live virus BRSV vaccine given to beef calves prior to weaning, at weaning or immediately after arrival in the feedlot was associated with a significant reduction in the treatment rate in one of three groups immunized prior to weaning or immediately after arrival in the feedlot.5 There was no significant effect of the vaccine on treatment rate in calves immunized at weaning, in calves immunized after arrival in a bull test station, or in yearlings vaccinated of calves twice with a killed whole-cell bacterin reduced the clinical and pathological effects of pneumonic pasteurellosis. However, there is little, if any, published evidence based on controlled field trials that such blanket recommendations are justifiable.

**REFERENCES**

and produce the lesions are complex and unclear. Viruses or mycoplasmas may act synergistically to allow the bacteria to be pathogenic. There is often a history of stressors such as:
- Transportation
- Mixing of groups of cattle from different sources
- Confinement of cattle
- Ineffective housing and ventilation.

**EPIDEMIOLOGY**

**Occurrence**

Pneumonic pasteurellosis is a common disease of young growing cattle in Europe, the UK, and North America. In Canada and the USA the disease occurs most commonly in recently weaned beef calves 6-8 months of age shortly after being placed into feedlots in the fall of the year. Nursing beef calves, yearlings, and mature dairy and beef cows may also be affected, but less frequently. Pneumonic pasteurellosis, also known as **shipping fever**, is an entity within the bovine respiratory disease complex, characterized clinically by acute bronchopneumonia with toxemia and pathologically by lobar, anteroventrally distributed, exudative pneumonia in which fibrin is usually a prominent part of the exudate and fibrinous pleuritis is common.

**Morbidity and mortality**

The morbidity may reach 35%, the case-fatality rate may range from 5-10%, and the population mortality rate may vary from 0.75-1.1%. However, these morbidity and mortality data may not be reliable because of wide variations in the methods used to calculate disease incidence and prevalence. A review of the literature of morbidity and mortality rates and disease occurrence in feedlot cattle in North America found deficiencies in the epidemiological data available from feedlots. Case definitions of clinical cases are often poorly defined. A summary of 14 comparable studies containing disease incidence rates in calves in the first few weeks following arrival in feedlots found wide variations in how the disease definitions and statistics were used. The incidence of morbidity ranged from 0-69% with most reports between 15% and 45%. The population mortality rate ranged from 0-15% with most reports between 1% and 5%. The peak incidence of disease occurs within the first 3 weeks after arrival of the calves in the feedlot. The most common clinical and pathological diagnosis was respiratory disease, often described as shipping fever.

In order to make valid assessments of morbidity and mortality rates, it is imperative that case definitions are stated clearly, the population at risk is precisely measured and the period of observation is stated or incorporated into the rate. The morbidity rates quoted for bovine respiratory disease are actually treatment rates based on treatment of animals that appear depressed, have a fever and have no signs to suggest disease of a body system other than the respiratory tract. Systematic methods of data collection from the customized records of large feedlots are now available and have been validated by the National Animal Health Monitoring System.

An observational study of the epidemiology of fatal fibrinous pneumonia in feedlot calves purchased from auction marts in western Canada and placed in a commercial feedlot between September 1 and December 31 over a 4-year period identified some valid information. Peak fibrinous pneumonia occurred approximately 16 days after arrival at the feedlot; the median number of days between arrival and the first treatment of fatal fibrinous pneumonia cases varied from 3-8 days. The fatal fibrinous pneumonia mortality varied 11-fold (0.25-2.73%) between years. The fatal fibrinous pneumonia proportionate mortality varied from 10-57%. Fully 75% of the calves that died of fibrinous pneumonia already were sick within 2 weeks after arrival. When the incidence of fatal fibrinous pneumonia was high (greater than 2%), the disease clustered, either within certain truckload groups of calves or within certain pens, or within both. Clustering could have been due to contagious factors, noncontagious factors, or both.

**Economic importance**

Pneumonic pasteurellosis is a major cause of economic loss in the feedlot industry. It is responsible for the largest cause of mortality in feedlots in North America. In addition to the death losses, the costs of treatment (which include the personnel involved in the detection and actual treatment, the drugs used and the vaccines) are considerable. While it has been assumed that there is a loss of production following the illness, this has not been documented. In fact, because of compensatory regrowth in animals that have recovered there may be no correlation between average daily gain, feed conversion and treatment.

**Risk factors**

**Animal risk factors**

The disease occurs most commonly in young growing cattle from 6 months to 2 years of age but all age groups are susceptible. Calves that are nonimmune to *M. haemolytica* are considered to be more susceptible to the disease than calves that have serum neutralizing anti-bodies to the organism and its cytotoxin. Calves that have recovered from the experimental disease are resistant to naturally occurring disease. In western Canada, auction market calves that originate from many different farms and are mixed at the market are at high risk. The calves may develop the disease before weaning if subjected to the stress of an early snowstorm in the late fall in Canada. Similar observations in single-suckled calves have been made in the UK.

The disease occurs commonly in outbreaks 7-10 days after cattle have arrived in the feedlot following stressful transport. This forms a major part of the `shipping fever' complex, which is a major hazard in the practice of rearing beef cattle on range country and then transporting them long distances to other centers for growing and finishing. However, in a western Canadian study, the distance that calves were transported by truck from the auction markets to the feedlot was not associated with an increased risk of fatal fibrinous pneumonia. The risk of fatal fibrinous pneumonia was just as high for calves arriving from nearby markets as for calves transported much greater distances.

Although the disease occurs most commonly in young beef cattle soon after their introduction to feedlots it is not uncommon in dairy herds, especially when recent introductions have been made or cattle are returned to their home farms after summer grazing on community pastures or exhibition at fairs. Herd outbreaks of peracute pleuropneumonia due to *M. haemolytica* have been reported in adult dairy cattle. Only adults were affected, many animals were affected, a high proportion of affected cows were in the immediate postcalving period, and all farms had purchased cows and/or heifers within the last 12 months. There was no history of transportation or movement of affected animals. Mature beef cows are also susceptible to pneumonic pasteurellosis if they are subjected to stressors during the summer months or in the fall of the year, usually associated with moving large groups to or from pasture during inclement weather.

Environmental and management risk factors

The mixing of cattle from different sources is an important risk factor. Mixing of recently weaned beef calves from different sources at auction markets was associated with an increased risk of fatal fibrinous pneumonia in calves moved to feedlots in western Canada, especially in November, shortly after auction sales had
The role of stress as a risk factor in shipping fever pneumonia has been examined experimentally. Experimental transportation and handling to mimic stress, followed by an aerosol of *M. haemolytica*, did not result in significant lesions of pneumonia but did make the animals susceptible to BHV-1. The effects of transportation and assembling of yearling beef calves can result in an increase in the levels of plasma fibrinogen, which is an indication of some stress. Deprivation of feed and water followed by confinement in unfamiliar surroundings also results in an increase in fibrinogen. The response of the animals was also dependent upon the previous environment and management applied to them before assembly and transportation.

Confinement in drafty or humid and poorly ventilated barns, exposure to inclement weather, transport, fatigue and deprivation from feed and water are commonly followed by outbreaks of the disease in cattle. An increase in virulence of the bacteria is often evident after animal passage; at the commencement of an outbreak only those animals that have been subjected to devitalizing influences are affected but the disease may subsequently spread to other animals in the group. There is little tendency for the disease to become an area problem, sporadic outbreaks occurring with the appearance of conditions favorable to the development of the disease.

Pathogen risk factors

The frequency of isolation of *Pasteurella* spp. from the nasal passages of normal healthy unstressed calves is low but increases as the animals are moved to an auction mart and then to a feedlot. It is difficult to establish long-term colonization of the nasal cavities of healthy, nonstressed calves with *M. haemolytica*. When calves are inoculated intranasally with IBRV or PI-3V, the nasal passages become much more susceptible to colonization with *M. haemolytica* even in the presence of antibodies to the organism in the serum and nasal secretion.

The prevalence of *M. haemolytica* biotype 1 in the nasal cavity and trachea can be low in beef calves from a closed herd that is maintained on range pastures, and serum antibody levels are also low. Over time there may be an increase in the frequency of isolation of the bacteria from healthy calves that were moved to pens, held in low population densities and maintained under low stress conditions. In some cases, serotype 2 predominates while the calves are on the farm, and serotype 1 predominates when the calves are in the feedlot and affected with pneumonia.

There are also relationships between the numbers of bacteria in the nasopharynx and the ambient temperature and humidity. In calves kept at a constant temperature of 16°C (60°F), the bacterial populations in the nasopharynx were at a minimum between 65% and 75% relative humidity and tended to rise at humidities outside that range.

The possibility that infection with several different viruses and mycoplasma may predispose to pneumonia pasteurellosis has been a subject of intense research activity and is presented in more detail under Pathogenesis. Seroepidemiological surveys of cattle in feedlots reveal that IBRV, PI-3C, BVDV, and BRSV were present, active, and associated with respiratory disease. The presence of antibody indicates current or recent exposure to the virus but does not indicate resistance. Cattle with low titers to IBRV and/or BRSV were at increased risk of subsequent treatment for bovine respiratory disease. Treated cattle also had greater increases to PI-3V and/or BVDV than control calves. While there is evidence that BVDV can experimentally affect certain immune mechanisms, there is little direct evidence that the virus is a major predisposing factor in the causation of naturally occurring pneumatic pasteurellosis. Seroepidemiological surveys indicate that seroconversion to BVDV is related to increased risk of respiratory disease at both individual and group levels. Serologically there is also evidence of a high prevalence of *M. bovis* and *M. dispar* in feedlot calves. But the relative importance of these pathogens as a cause and effect relationship is controversial.

Bovine coronavirus has been associated with some natural outbreaks of shipping fever in feedlot cattle. Up to 80% of affected animals shed bovine coronavirus from their nasal cavities when the infection rate with *Pasteurella* spp. was low. The virulence factors of *M. haemolytica* include fimbriae, polysaccharide capsule, outer membrane proteins, endotoxin (lipopolysaccharide), and leukotoxin, which are described later under pathogenesis. The genes that code for the various virulence factors of *M. haemolytica* have been cloned for detailed characterization. Fibrinogen-binding proteins may be present in the culture supernatants of *M. haemolytica* serotype 1 and *Pasteurella trehalosi* serotype 10. These bacteria may contribute directly to fibrin formation and the development of fibrous pneumonia.

*M. haemolytica* serotypes A1 and A2 can survive for long periods of time in relatively low-nutrient in vivo fluids. Both strains survived for at least 244 days in ovine and 156 days in bovine tracheobronchial washings, respectively. This may provide an explanation for the long survival of the organism in the nasopharynx of ruminants.

Tetracycline resistance (tet) genes have been found in isolates of *P. multocida*, *M. haemolytica*, *Mannheimia glucosida*, and *Mannheimia varigena* from cases of respiratory disease in cattle and pigs in Germany. Tetracycline resistance in *P. multocida* and *M. haemolytica* is mediated by at least three different tet genes, most of which are located on the chromosomes. A new tet (H)-carrying plasmid has been identified, and tet (B) has been detected in *P. multocida*, and tet (D) in *M. haemolytica*.

**Immune mechanisms**

Calves that have recovered from the experimental disease are resistant to naturally occurring disease. Numerous *M. haemolytica* antigens may stimulate the immune response and resistance to disease. These antigens include capsular polysaccharide, leukotoxin, and surface antigens, including iron-regulated proteins, a serotype-specific outer membrane protein, and several other antigens that are less well defined. High antibody responses to *M. haemolytica* surface extract proteins are correlated with resistance to experimental pneumonic pasteurellosis. Resistance to experimental challenge with the organism correlates directly with serum cytotoxin neutralizing titers. Cattle cying from pneumonic pasteurellosis may have lower levels of cytotoxin neutralizing antibody than animals from the same group dying from other causes. Aerosol exposure of calves with *M. haemolytica* results in the development of toxin neutralizing antibodies in pulmonary lavage samples and an accompanying increase in serum neutralizing titer. Since aerosol exposure of calves to viable *M. haemolytica* elicits a protective immune response characterized by enhanced clearance of the organism from the lung and by protection against fibrous pneumonia, it is possible that the presence of pre-existing antibodies to the leukotoxin in the lungs may provide immunity by protecting phagocytic leukocytes from the leukotoxin and by promoting phagocytosis and intracellular killing of the organism.

Passive immunization with antibodies to whole *M. haemolytica* or leukotoxin-containing supernatants provides protection against experimentally induced pneumonic pasteurellosis similar to the protection provided by active immunization with these antigens. In contrast, antibodies to lipopolysaccharide provided little protection against challenge.
Cattle exposed to live organisms produce antibodies to both cell surface antigens and cytotoxin, whereas exposure to the killed vaccine results in the production of antibodies primarily to cell surface antigens.

The experimental lung challenge of calves with formalin-killed *P. multocida* does not provide subsequent protection to challenge with live *P. multocida*.

**Method of transmission**

Transmission of pasteurellae probably occurs by the inhalation of infected droplets coughed up or exhaled by infected animals, which may be clinical cases or recovered carriers in which the infection persists in the upper respiratory tract. *M. haemolytica* and *P. multocida* are highly susceptible to environmental influences and it is unlikely that mediate contagion is an important factor in the spread of the disease. When conditions are optimal, particularly when cattle are closely confined in inadequately ventilated barns, or when overcrowded in trucks and trains, or held for long periods in holding pens in feedlots, the disease may spread very quickly and affect a high proportion of the herd within 48 hours. In animals at pasture, the rate of spread may be much slower.

**PATHOGENESIS**

The literature on pathogenesis, including the extensive experimental work done on the role of the virulence factors, has been reviewed.

**Colonization of upper and lower respiratory tracts**

Considerable research has centered on determining how the pasteurellae, which are part of the normal flora of the upper respiratory tract, colonize first the upper respiratory tract then the lower respiratory tract. Under normal conditions the bovine lung is relatively free of pasteurellae because of an effective lung clearance mechanism. The current hypothesis is that a combination of a viral infection of the respiratory tract and/or devitalizing influences from transportation, temporary starvation, weaning, rapid fluctuations in ambient temperature, the mixing of cattle from different origins and the excessive handling of cattle after arrival in a feedlot can all collectively promote an increase in the total numbers and virulence of pasteurellae in the nasopharynx, which then enter the lung. In clinically normal cattle, *M. haemolytica* are present in low numbers in the tonsil and nasal passages and those that are isolated are predominantly biotype A serotype 2 which is rarely associated with shipping fever. Exposure of healthy cattle to stressors such as viral infection, change in management practices and environmental changes leads to an explosive growth and selective colonization by *M. haemolytica* A 1 in the upper respiratory tract.

The experimental intranasal exposure of calves to a leukotoxin-deficient *M. haemolytica* elicits an increase in the serum antibody titers against the organism and decreased colonization of the nasopharynx by wild-type *M. haemolytica.*

This could allow an immune response to develop before transportation and offer protection from nasopharyngeal colonization and pneumonia by wild-type *M. haemolytica.*

Under normal conditions, alveolar macrophages will effectively clear pasteurellae from the alveoli by phagocytic mechanisms. When the large numbers of organisms enter and colonize the lung they interact with alveolar macrophages. Neutrophils enter the lung within the first few hours after bacterial inoculation.

Bovine alveolar macrophages release superoxide anion when exposed to *M. haemolytica* and the response is dependent on the presence of opsonizing antibody and the quantity of organisms presented to the phagocyte. This may have a major role in the pathogenesis of the acute lung injury associated with pneumonic pasteurellosis. It is an important mechanism by which this phagocyte can initiate microbicidal activity and may provide clues to further study of the defense mechanisms of the lung.

**Virulence factors and cellular and humoral reactions**

The lung injury caused by the organisms after entry into the lung is dependent on important virulence factors.

Four virulence factors have been associated with *M. haemolytica*:

- **Fimbriae**
- **A polysaccharide capsule**
- **Endotoxin (lipopolysaccharide)**
- **Leukotoxin.**

The interactions of these virulence factors contribute to the pathogenesis of the disease. **Fimbriae** enhance the colonization of the upper respiratory tract. The **polysaccharide capsule** of the organism inhibits complement-mediated serum killing as well as phagocytosis and intracellular killing of the organism. The capsule also enhances neutrophil-directed migration and adhesion of the organism to alveolar epithelium. The **lipopolysaccharide** or endotoxin can alter bovine leukocytes functions and is directly toxic to bovine endothelium. It also modifies cardiopulmonary hemodynamics and elevates circulatory prostanoids, serotonin, cAMP, and cGMP. The organism induces morphological alterations in bovine pulmonary endothelial cells, the effects of which can be partially inhibited by indomethacin. Tissue factor is involved in intra-alveolar fibrin deposition and coagulopathy associated with pneumonic pasteurellosis in cattle.

The migration and activation of neutrophils in inflamed tissue are regulated by a complex network of interactions among cytokines, leukocytes, vascular endothelium, cellular adhesion molecules, and soluble chemotactic factors. The inflammatory cytokines tumor necrosis factor alpha, interleukin (IL)-1 beta, and IL-8 play a central role in the initiation and orchestration of these interactions.

IL-8 is the dominant cytokine expressed within the lungs during the acute phase of pneumonic pasteurellosis.

Neutrophil-mediated inflammation in cattle with pneumonic pasteurellosis contributes to the development of severe disease rather than effective clearing of invading *M. haemolytica*. Leukotoxin is one of the major virulence factors of *M. haemolytica* responsible for impaired function of neutrophils.

The **lipopolysaccharide or endotoxin** of *M. haemolytica* is capable of causing direct injury to bovine pulmonary arterial endothelial cells, which may be a contributing pathogenetic mechanism. Endotoxin interacts with numerous cell types and humoral mediator systems, resulting in widespread injury to the lung. Endotoxin can readily cross the alveolar wall either from the air or blood and interact with cells and humoral mediators. The endotoxin can be found in the neutrophils in the alveolus, interstitial tissue, and capillary lumen; in intra-vascular, interstitial, and alveolar macrophages; in endothelial cells; and on alveolar epithelial cell surfaces. The interaction of endotoxin with cells leads to cell activation and death.

**Leukotoxin** is produced by all known serotypes and is a heat-labile protein exotoxin, a pore-forming cytolsin that affects resident leukocytes and platelets. The bacterium produces the leukotoxin, with maximum production occurring during the log phase of growth, peaking after 6 hours of incubation. Following the inhalation of *M. haemolytica* into the lung there is an accumulation of neutrophils that, when destroyed by leukotoxin, result in the release of proteolytic enzymes, oxidant products, and basic proteins, which degrade cellular membranes, increasing capillary permeability, which results in fluid accumulation in the interstitium of the alveolar wall, alveolar wall necrosis, and pulmonary edema. Leukotoxin also induces histamine release from bovine mast cells. The importance of the neutrophil is supported...
by experimental evidence that depletion of blood neutrophils in calves made the animals much less susceptible to pulmonary injury following intratracheal inoculation of *M. haemolytica*.

Exposure to low concentrations of *Haemolyticum* leukotoxin in vitro induces apoptosis in bovine leukocytes. Apoptosis is a process of cell death distinguished from necrosis by various morphological and biochemical criteria. These include chromatin collapse with subsequent chromatin margination in crescent-shaped masses around the periphery of the nucleus, blebbing of the cytoplasmic membrane, and internucleosomal cleavage of DNA into nucleosome-sized fragments. This may represent an important mechanism by which *M. haemolytica* overwheels host defenses.

Tilmicosin, a very effective antibiotic for the treatment of pneumonic pasteurellosis, induces apoptosis in neutrophils, which results in reduced levels of the potent proinflammatory mediator leukotriene B4 in lung fields of infected calves treated with tilmicosin. The tilmicosin-induced apoptosis in neutrophils directly enhances phagocytic removal of these cells by macrophages.

Supernatants of the organism can also cause rapid cytolysis of platelets. The genes that code for the synthesis and secretion of the leukotoxin have been cloned. It is a highly immunogenic protein that is produced by all 15 serotypes of *M. haemolytica*. Antiserum raised to the 105 kDa protein neutralizes its leukotoxic activity. Cattle with high leukotoxin antibody titters have higher survival rates in natural and experimental cases of pneumonic pasteurellosis than animals with low antibody titters. The development of efficacious vaccines will probably depend on using leukotoxin antigens and bacterial surface components to elicit maximum resistance against pneumonic pasteurellosis. Assay tests for determination of cytotoxic neutralizing antibody titers in cattle sera are described. There is positive correlation between ELISA titters to cytotoxicity and protection to experimental pneumonic pasteurellosis.

**Experimental pneumonic pasteurellosis**

In an attempt to understand the pathogenesis of shipping fever pneumonia the experimental disease has been reproduced using several different methods: the most commonly used is the sequential aerosol infection of calves with either the PI-3 virus or the IBR virus followed by an aerosol of *M. haemolytica* 3 days or more later. Exposure of calves to aerosols of PI-3V followed by *M. haemolytica* at intervals of 3-13 days later results in a purulent bronchopneumonia. The virus interferes with the lung clearance of *M. haemolytica* when an aerosol of the bacteria is given 7 days following the viral infection. There is little interference after only 3 days and a moderate degree at 11 days.

Pneumonic pasteurellosis similar to the naturally occurring disease can be reproduced experimentally by exposing calves sequentially to aerosols of BHV-1 and *M. haemolytica* 4 days apart. The virus infection partly destroys the clearance mechanism of the respiratory tract epithelium and exacerbates the subsequent *M. haemolytica* infection. Both antigens can be detected by immunohistochemical methods in the bronchoaveolar fluid cells.

The viral–bacterial synergism is associated with the release of cytokines, which attract more leukocytes and increase leukocyte expression of CD11a/CD18. In this experimental model, vaccination of the animal against the virus before challenge with the viral–bacterial aerosol sequence is protective. The interaction between the IBR virus and *M. haemolytica* can persist for up to 30 days after infection with the virus. A sequential aerosol infection of IBR and *P. multocida* or *P. multocida* alone, can also result in pneumonia. Experimental in vitro studies indicate that IBR infection does not have a direct effect on the ability of neutrophils to phagocytose *M. haemolytica* but rather that there is an indirect effect, perhaps through the release of mediators that have an effect on phagocyte function. Large amounts of interferon are produced throughout the course of IBR infection, which reduces chemotaxis and elevates oxidase activity by bovine neutrophils.

Pneumonic pasteurellosis can also be reproduced by intratracheal instillation of live *M. haemolytica* into conscious calves results in acute cardiovascular changes consisting of two systemic hypodynamic and pulmonary vasoconstrictive phases. Injection of metronidazole (a 5-HT_2_ receptor antagonist) 2 hours after inoculation abolishes the late increases in pulmonary arterial pressure and pulmonary vascular resistance.

**Synergism between pathogens**

Experimentally, synergism may occur between *M. haemolytica* and *M. bovis* in producing pneumonia in gnotobiotic calves and not in conventional calves.

The role of BVDV in outbreaks of pneumonic pasteurellosis is uncertain. In one study the virus did not impair the pulmonary clearance of *M. haemolytica*. In a different study the endobronchial inoculation of calves with *M. haemolytica* sequentially 5 days apart resulted in a severe fibrinopurulent bronchopneumonia and pleuritis involving up to 75% of the total lung volume. Endobronchial inoculation of the organism only caused a localized noninvasive lesion in the lungs.

In summary, pneumonic pasteurellosis can be reproduced experimentally without a preceding virus infection, and it is likely that the naturally occurring disease can also occur withou precedine viral infection.

The terminal lesion is an acute fibrinous pleuropneumonia. The ventral aspects of the apical and cardiac lobes of the lungs are most commonly affected; in advanced cases a greater portion of the lung becomes affected and other lobes of the lung become involved. Consolidation of affected lobes results in loud breath sounds, and the exudative nature of the lesion causes crackles. The pleuritis causes thoracic pain and pleuritic function rubs. Death is due to hypoxemia and toxemia. Complications include pulmonary abscessation, chronic pleuritis with or without pleural effusion, bronchiectasis, pericarditis and, rarely, congestive heart failure due to cor pulmonale.

**CLINICAL FINDINGS**

The spectrum of clinical findings depends in part on whether the disease is occurring in groups of young cattle in a large commercial feedlot, in a small farm feedlot or in individual animals such as lactating dairy cows, in which illness is more easily recognized based on milk production and feed intake. In the feedlot situation, affected animals must be identified primarily by visual observation followed by closer physical examination.

**Feedlot**

In the feedlot, the disease usually occurs within 10-14 days after the animals have been stressed or have arrived in the feedlot. It may occur within 1 day after arrival if the animals have been incubating the disease agent in the previous feedlot or on the farm of origin. Affected animals are standing or lying quietly in the feedlot pens. Occasionally, they may be depressed in which case the nasal passages are more congested than normal or may be discharging mucus or blood. The animals may have shallow, rapid or labored breathing.

The pulse rate is usually normal but may be increased. Rectal temperature may be elevated. The animals show a marked loss of appetite and feed intake. The clinical signs of pneumonia may be manifested by a cough, dyspnoea, tracheal crepitations, decreased milk production, signs of depression and lameness. Chronic cases may show signs of emaciation.
Diseases associated with *Pasteurella* species

**Close physical examination**

The relationships between clinical and pathological findings of disease in calves experimentally infected with *M. haemolytica* type A1 indicated that the respiratory rate, rectal temperature and clinical scores are significantly correlated with the extent of consolidation of the lungs. The respiratory rate increased from 30 per minute up to 70 per minute as the percentage of lung consolidation increased from 10% to 50%

The typical case of pneumonia pasteurellosis reveals a fever of 40–41°C (104–106°F), bilateral mucopurulent nasal discharge, gaunt abdomen with rumen atony, coughing, varying degrees of polypnea and dyspnea, and evidence of bronchopneumonia. In the early stages there are loud breath sounds audible over the anterior and ventral parts of the lungs. As the disease progresses these breath sounds become louder and extend over a greater area; cracks become audible, followed by wheezes in a few days, especially in chronic cases. Pleuritic friction rubs may be audible, although their absence does not preclude the presence of extensive adherent pleuritis. In severe cases or those of several days' duration the dyspnea is marked, commonly with an expiratory grunt, although the respiratory rate may not be elevated.

The course of the disease is only 2–4 days. If treated early, affected cattle recover in 24–48 hours but severe cases and those that have been ill for a few days before being treated may die or become chronically affected in spite of prolonged therapy. Some cattle recover spontaneously without treatment

A mild diarrhea may be present in some cases but is usually of no consequence. On an affected farm, calves may be affected with pneumonia and young calves may die of septicaemia without having shown previous signs of illness.

**CLINICAL PATHOLOGY**

**Bacterial culture**

Nasal swabs taken from clinical cases before treatment often yield a pure culture of pasteurellas, but *M. haemolytica* biotype A is the most common isolate obtained from cattle with acute pneumonic pasteurellosis. The same serotype can usually be isolated from in-contact and apparently healthy calves. The antimicrobial sensitivity of the pasteurellas isolated can be determined, but interpretation of the results is often difficult because it is not known whether the isolates from nasal swabs represent those causing the lesions. Significant differences may exist between the antimicrobial sensitivities of isolates from nasopharyngeal swabs and those from the lung tissues. Thus it is not yet possible to recommend routine culturing and antimicrobial sensitivity determination of pasteurellas from nasal cavity or nasopharyngeal mucus from cattle with acute shipping fever pneumonia. At the individual animal level, nasopharyngeal swabs and bronchoalveolar lavage reveal only moderate agreement; at the group level the isolation rates of various organisms are similar. In healthy calves monitored from the farm to the feedlot there was no relationship between the nasal flora and pulmonary lesions. There is some evidence that antimicrobial resistance is emerging among field isolates of *M. haemolytica* and plasmid-mediated antimicrobial resistance is now known to occur.

**Hematology**

Plasma fibrinogen concentrations are elevated, paralleling the increase in body temperature, and are a more reliable indication of the presence of the lesion than clinical assessment. Young cattle with clinical signs of acute respiratory disease, a fibrinogen concentration greater than 0.7 g/dL, and a temperature greater than 40°C (104°F) are likely to have pneumonic pasteurellosis. Leukocyte counts are of little value, as a leukocytosis and neutrophilia occur in some animals but in others there may be a neutropenia or no significant change. Acute phase proteins are increased within 24 hours following experimental intratracheal inoculation of *M. haemolytica* into calves. The availability

does not the animal has pneumonia and requires treatment, some animals are treated unnecessarily. This is a problem in large feedlots that process many 'sick' animals daily based on the clinical findings and a fever, the sensitivity of detection of the presence of the lesion than

...occurred ill for a few days before being treated may die or become chronically affected in spite of prolonged therapy. Some cattle recover spontaneously without treatment.
of a rapid test for acute phase proteins could assist in the field diagnosis of the disease and its possible differentiation from similar diseases.

**NECROPSY FINDINGS**

There is marked pulmonary consolidation, usually involving at least the anteroventral third of the lungs. The stage of pneumonia varies within the affected tissue, commencing with congestion and edema and passing through various stages of airway consolidation with serofibrinous exudation in the interlobular spaces. A catarhal bronchitis and bronchiolitis, and a fibrinous pleuritis are usually present and may be accompanied by a fibrinous pericarditis. The lung is firm and the cut surface usually reveals an irregular, variegated pattern of red, white, and gray tissue due to hemorrhage, necrosis, and consolidation. Coagulation necrosis of pulmonary lungs is the most characteristic lesion in pneumonic pasteurellosis. In chronic cases there are residual lesions of bronchopneumonia with overlying pleural adhesions. Occasionally, sequestra of necrotic lung tissue are found. *P. multocida* causes a fibrino-purulent bronchopneumonia without the multifocal coagulation necrosis that is characteristic of the fibrinous lobular pneumonia associated with *M. haemolytica*.

The sequential gross and microscopic lesions of experimental bovine pneumonic pasteurellosis have been described and may provide guidelines for aging the lesions in naturally occurring cases. On days 2–3 after infection the lesion is characterized by soft gray-purple consolidation; on day 6 the affected areas are firm and nodular; on days 9–10 the nodular lesions are more prominent and fibrinous tissue encapsulates the lesions and becomes obvious. The initial microscopic changes consist of flooding of the alveoli with edema, fibrin, and hemorrhage. Large numbers of neutrophils and macrophages move into the alveoli by day 2. The classical lesion is visible by day 4 and consists of necrotic tissue surrounded by a dark zone of inflammatory cells. The elongate, ‘oat-cell’ profile of some of these leukocytes is a useful marker in culture-negative cases. In nonfatal cases a walling-off reaction by fibrinous tissue isolates the necrotic tissue. Determination of the age of the lesions by gross and/or microscopic examination may assist in correlating the occurrence of the disease with specific health management procedures in the herd. In feedlot cattle, determining the age of bacterial pneumonia can help to assess whether or not the pneumonia was present in the animal on arrival or if treatment failure resulted from late detection or from inadequate drug therapy. The degree of necrosis and fibrosis are the main lesions used to age pneumonia.39

In general, *M. haemolytica* causes a fibrinous pleuropneumonia with extensive thrombosis of interstitial lymph vessels and limited evidence of bronchitis and bronchiolitis. In contrast, broncho-pneumonia due to *P. multocida* is associated with a suppurative bronchitis, minor thrombosis of interstitial lymph vessels, and considerably less exudation of fibrin.

The organism is easily cultured from acute, untreated cases but other species of bacteria, including *anaerobes*, are often found in more chronic cases. More sophisticated tests such as PCR and immunoperoxidase techniques are available for the detection of *M. haemolytica* but are seldom required in diagnostic cases.

**Samples for confirmation of diagnosis**

Bacteriology – lung, bronchial lymph node (CULT)

Histology – formalin-fixed lung (LM).

**DIFFERENTIAL DIAGNOSIS**

The differential clinical diagnosis of pneumonic pasteurellosis is summarized in Table 18.5.

As a general guideline the common pneumonias of cattle may be divided into bronchial, interstitial, and hematogenous.

- The **bronchial pneumonias** include pneumonic pasteurellosis and other less common bacterial pneumonias characterized by toxemia and shallow respiration and a good response to early treatment.

- The **interstitial pneumonias** include the viral and parasitic pneumonias, and acute interstitial pneumonias characterized by marked respiratory distress and a slow response or no response to treatment. In viral pneumonias the animals may die acutely in a few days or recover over a period of several days.

- The **hematogenous pneumonias** are associated with venous thrombosis and pulmonary aneurysm and are characterized by acute respiratory distress and hemoptysis and no response to treatment.

**Pneumonic pasteurellosis of cattle** is an acute, toxemic bronchopneumonia with a high fever and a good response to treatment in the early stages. Depression and anorexia are common. The disease is most common in young beef calves that have been recently stressed following weaning or mixed in auction markets and shipped to feedlots. The disease can also occur in mature cattle as a primary or secondary pneumonia. In **viral interstitial pneumonia** of calves, young and adult cattle there is characteristic dyspnea, a moderate fever, only a mild toxemia, loud breath sounds over the ventral aspects of the lungs followed by crackles and wheezes in a few days, and recovery may take several days. Pneumonia due to BRSV may be mild with uneventful recovery or severe with dyspnea and subcutaneous emphysema and a high case-fatality rate.39

**Lungworm pneumonia** occurs most commonly in young pastured cattle and is characterized by dyspnea, coughing, only mild toxemia and a moderate or normal temperature; the course may last several days. Usually many cattle are affected. Crackles and wheezes are usually audible over the dorsal aspects of the lungs and the response to treatment is usually favorable if treatment is initiated early when signs are first noticed.

**Less common causes of acute pneumonia in calves and young cattle** include infection with Klebsiella pneumoniae, Streptococcus spp., and Fusobacterium necrophorum, all of which are characterized by a bronchopneumonia indistinguishable clinically from pneumonic pasteurellosis.

**Epidemic acute interstitial pneumonia** (fog fever) usually occurs in outbreaks in pastured cattle that have been moved from dry to lush pasture (or just a different species of pasture or on to a recently harvested cereal grain field); the onset is sudden, some cattle may be found dead, while others are in severe respiratory distress with an expiratory grunt.

**Infectious bovine rhinotracheitis** is characterized by rhinitis, usually with discrete lesions in the nares, tracheitis, loud coughing, high fever and no toxemia unless secondary bacterial pneumonia is present. Recovery usually occurs gradually after 4–7 days.

**Contagious bovine pleuropneumonia** resembles pneumonic pasteurellosis but occurs in plague form; there is severe, painful, toxemic pleuropneumonia and the case fatality rate is high.

**TREATMENT**

**Antimicrobial therapy**

The recommendations for the treatment of bovine pneumonic pasteurellosis are based on clinical experience and the results of clinical field trials.

About 85–90% of affected cattle recover within 24 hours if treated with antimicrobials such as oxytetracycline, tilmicosin, trimethoprim–sulfadoxine, the sulfonamides, and penicillin. Broad-spectrum antimicrobials are used most commonly. One treatment is usually adequate and most economical for most cases but severely affected cattle or those that relapse require treatment daily, or even two to three times daily, depending upon the drug used, for up to 3–5 days.

**Choice of antimicrobial**

This will depend on the cost, availability, expected efficacy based on previous experience with the antimicrobial in a...
particular area, ease of administration, frequency of administration required, concentrations of the antimicrobial that can be achieved in the lung tissues of affected animals, and length of the withdrawal period required before slaughter or withholding of milk in lactating dairy cattle. The choice of antimicrobial also depends on the concentrations that can be achieved in the lung tissues of affected animals. The concentrations of oxytetracyclines are higher in pulmonary lung than in normal lung. Pharmacokinetic studies of oxytetracycline in experimental pneumonia pasturellosis indicates the need for observance of 12-hour dose intervals.

The antimicrobials and their dosage schedule in Table 18.6 are recommended as a guideline. The efficacies of oxytetracycline, penicillin, and trimethoprim-sulfadiazine are not significantly different for the treatment of undifferentiated bovine respiratory disease in cattle within the first 28 days after arrival in the feedlot. The response, relapse, and case fatality rates overall were 85.7%, 14.8%, and 1.4%, respectively. In some studies, the use of trimethoprim-sulfadiazine resulted in fewer days of treatment compared to penicillin and oxytetracycline.

Tilmicosin, a semisynthetic macrolide antimicrobial, is highly effective as a single subcutaneous injection at 10 mg/kg BW. Tilmicosin is effective in treating experimentally induced pneumonia pasturellosis as measured by alleviation of clinical signs, reduction in extent of lesions at necropsy and the presence of viable bacteria from the lung. Concentrations substantially above MIC for *M. haemolytica* were present in the lung tissue even at 72 hours following a single subcutaneous injection of 10 mg/kg BW. Tilmicosin rapidly accumulates in lung tissue and significantly higher concentrations are found in infected pulmonary tissue than in normal lung. Uniquely, tilmicosin effectively controls *M. haemolytica* infection, induces neutrophil apoptosis, reduces pulmonary inflammation and does not affect neutrophil infiltration or function. Tilmicosin-induced peripheral neutrophil apoptosis occurs regardless of the presence or absence of live *M. haemolytica*, exhibits at least some degree of drug specificity and promotes phagocytic clearance of dying inflammatory cells.

Tilmicosin is also effective in reducing the population of *M. haemolytica* colonizing the nasal cavities of calves with respiratory disease. By reducing colonization, prophylactic use of tilmicosin before transportation or at the time of arrival at a feedlot is likely to reduce the incidence of acute respiratory disease in animals during the first several days after arrival. Tilmicosin and difloxacin did not differ in their effect on mean body temperature of beef calves with experimental pneumonia pasturellosis. Some studies have shown that tilmicosin has no effect on neutrophil function or apoptosis.

Tilmicosin was highly effective as a single-dose treatment of bacterial pneumonia secondary to severe BRSV pneumonia in weaned beef calves. Florfenicol, an analog of thiamphenicol, is highly effective for the treatment of acute undifferentiated respiratory disease of feedlot cattle and its use will become widespread. Florfenicol and tilmicosin are comparable in the treatment of undifferentiated bovine respiratory disease in western Canada.

Enrofloxacin at a dose of 2.5–5.0 mg/kg BW subcutaneously daily for 3–5 days or 7.5–12.5 mg/kg BW subcutaneously is effective. Difloxacin and enrofloxacin are equally effective for treatment of the experimental disease. Difloxacin is rapidly distributed to the lungs and high tissue concentrations are achieved in the pulmonary lung, including areas of consolidation. In calves with experimental pneumonia pasturellosis, a single dose intravenously is more effective than the same dose administered by continuous infusion.

Ceftiofur preparations are being evaluated. Ceftiofur crystalline-free acid sterile suspension (CCFA-SS), a long-acting ceftiofur at 4.4–6.6 mg ceftiofur equivalents/kg administered subcutaneously in the middle third of the posterior aspect of the ear is effective, safe and practical for the treatment of experimental pneumonia pasturellosis and the control and treatment of bovine respiratory disease in feedlot cattle.

A rapidly disintegrating bolus formulation of baquilorip (an antifolate compound) and sulfadimidine was effective for the treatment of experimental pneumonia pasturellosis. The baquilorip is absorbed effectively and is synergistic with sulfonamides.

**Antimicrobial sensitivity**

The antimicrobial sensitivity of *M. haemolytica* varies, depending on the geographical origin of the animals and the previous use of the drug in the herd or the feedlot. Most isolates of *M. haemolytica* have some degree of multiple antimicrobial resistance, associated with continued use.

A 4-year survey of antimicrobial sensitivity trends for pathogens isolated from cattle with respiratory disease in North America based on MIC determinations using a broth microdilution method, indicated that, overall, resistance to ampicillin, tetracycline, erythromycin, and sulfamethazine was frequently encountered among isolates of *M. haemolytica* and *P. multocida*. There was widespread resistance to erythromycin, which, because of cross-resistance, may account for the wide variation in sensitivity to tilmicosin. Ceftiofur was very active against the pathogens.

Ampicillin- and tetracycline-resistant *Pasteurella* isolates from dairy cattle (dairy herds and calf ranches) with pneumonia were spatially clustered within certain geographical areas in California. The percentage of *M. haemolytica* isolates resistant to ampicillin was 21.3%; to *P. multocida*, 12.3%. The percentage of *M. haemolytica* isolates resistant to

*Diseases associated with *Pasteurella* species*
tetracycline was 37%; to *P. multocida*, 52.5%. This reinforces the need to establish regional estimates of percentages of bacterial isolates which are susceptible to commonly used antimicrobials.

Early identification of affected animals in feedlots
Where large numbers of cattle are involved, early identification is crucial to successful therapy. Affected animals should be removed from their pen, examined, treated, identified with a suitable tag for reference purposes and placed in a hospital pen until recovered. This avoids confusion in deciding which animal requires treatment the next day. The duration of treatment will depend on the severity of the individual case, the response achieved in the first few days, the economic worth of the animal, the extent of complications that may be present, such as pleurisy, pulmonary abscesses, and bronchiectasis, and the results that the veterinarian may expect from prolonged therapy in difficult cases.

Animal identification
Identification of every animal in the feedlot with a unique ear tag when it arrives in the lot, and use of a chute-side computerized records system allows the collection and collation of animal health reports on individual animals, and on pens or groups of animals. Large commercial feedlots now have computerized record systems, which have replaced the manual card system. The case abstract of each animal will include the number of times it has been examined and treated, its body temperature and diagnosis. The abstract is useful when doing a necropsy on animals that have been treated and died. The epidemic curve can be calculated from the number of animals identified each day from each pen. From the cumulative treatment data, the computer can provide information on the diagnostic capability of identifying sick animals based on their body temperature when they were examined the first time, the treatment response, relapses and when they occurred, and mortality rates.

Medication of feed and water supplies
There is much interest in mass medication of the drinking water or feed supply or both. The rationale is that the medication of the feed or water would successfully abort an outbreak by treating those animals incubating the disease, provide convalescent therapy to those that have already been treated individually, and deal with mild cases before they become acutely ill and need individual treatment. However, there are problems. The amount of water that cattle drink is directly proportional to feed consumption. If they are inappetent or anorexic, water consumption will decline to only maintenance requirements and therapeutic levels of drug will not be achieved if the concentration in the water is provided at a level for normal consumption. The other major problem is the provision of a uniform concentration of drug in the water supply, either through automatic water proportioners in the waterline or placing the drug directly into water tanks. Both can be unreliable. There is a need for the development of reliable methods of mass medication of the feed and water supplies of cattle.

Mass medication of individual animals
The individual treatment of all in-contact animals in an affected group may be useful in controlling an outbreak of the disease. If the rate of new cases each day ranges from 5–10% of the group, each animal in the remainder of the group may be treated with a long-acting preparation of oxytetracycline at the rate of 20 mg/kg BW intramuscularly. Trimethoprim at 10 mg/kg BW subcutaneously is also effective for mass medication of individual animals. This form of group medication will treat cases during the subclinical stages and may prevent new infections. Long-acting oxytetracycline at the same dose rate is also effective for the treatment of clinical cases and reduces the labor and the stress of handling associated with daily treatment, which may be required in severe cases.

Anti-inflammatory agents
Corticosteroids and nonsteroidal anti-inflammatory drugs (NSAIDs) are used by some veterinarians as an ancillary treatment for severe cases. The rationale is their anti-inflammatory effect but no data are available to support the field experience of some veterinarians that they are efficacious and economical.

Failure to respond
The causes of failure to respond to therapy include:
- Advanced pneumonia before treatment is initiated
- Presence of viral or interstitial pneumonia or some other pneumonia that is not responsive to antimicrobials
- Inadequate dose of antimicrobials
- Antimicrobial resistance of the bacteria
- Complications such as pulmonary abscess, bronchiectasis, and pleuritis.

CONTROL
Satisfactory economical control of the disease depends on the successful integration of management and perhaps the use of vaccines and antimicrobials prophylactically. It is unrealistic to depend on a vaccine, an antimicrobial or a single management technique to control the disease. Successful control begins with the adoption of effective management techniques when beef calves are still on the range, the judicious use of efficacious vaccines, and care in handling and transportation of cattle.

Management strategies
Preconditioning programs
Because of the common occurrence of the disease at the time of shipment from the range to the feedlot, much attention has been given to reducing the incidence of disease at this time. This led to the development in North America of the concept of preconditioning. The objective of preconditioning was to prepare the weaned calf for the feedlot environment by vaccinating it for all the commonly anticipated diseases before weaning and distributing all stressful procedures such as castration, dehorning, branding, and deworming over a period of time rather than concentrating these at weaning time. Weaning at least 2 weeks before shipment was also considered a desirable practice. This was to result in a weaned calf that could be moved into a feedlot in which the feed bunks and water bowls would not be strange but familiar and the calf would adjust quickly. The most common vaccinations were for IBRV, PI-3V, BVDV, and clostridial disease. In some situations, vaccines were also vacinnated for *H. somni* and BRV, and against pneumonic pasteurellosis.

Preconditioning has not been widely accepted because its economic value has not been proven. Nevertheless, the procedures involved promote health and can be recommended even though their economic value remains to be determined. Some reports claim that preconditioning can benefit both cow–calf producers and the buyers of preconditioned calves. Heavier calves at sale, low cost of average daily gain, and the price differential have the greatest impact on increased net return. Preconditioning programs have motivated cow–calf producers to examine preconditioning as a method to improve the marketability of their calves and to develop a reputation for a high-quality product. Calves perform better in the feedlot if the stresses from dehorning, castration, and vaccination occur at the same time, but before the stress of weaning occurs.

Weaning procedures
Beef calves should be weaned well in advance of anticipated inclement weather. This is especially true in North America, where the fall months can be cold and windy, and snowstorms can occur. A
common successful practice is to begin feeding hay and providing water to calves at least 2 weeks before weaning in the same corral or paddock into which they will subsequently be weaned. Following such a weaning program, the calves require only a minimum of adjustment: the only adjustment necessary should be the loss of their dams. Recently weaned calves should be observed at least twice daily for evidence of respiratory disease and treated promptly if necessary. They should not be transported long distances until they appear to be healthy and are eating liberal quantities of hay and drinking water normally. During transportation, liberal quantities of bedding are necessary and cattle should not be without feed and water for more than 24–30 hours. For long trips, calves should be rested for 8–12 hours and fed water and hay at intervals of 24 hours. This will minimize the considerable loss of body weight due to shrinkage and the effects of temporary starvation.

Creep feeding
The use of creep feed for calves for several weeks prior to weaning has been successful but may not always be economical. A high-energy ration containing cereal grains, a protein supplement and the necessary vitamins and minerals is provided for the calves in a creep arrangement to which the dams do not have access. At weaning time the dams are removed from the calves and the stress on the calves is minimal. This program has been very successful for purebred herds, where it may be economical, but in commercial herds it is only economic when the market value of the calves warrants it.

Conditioning programs
In the absence of preconditioning programs, conditioning programs have become the usual procedure for preparing beef calves or yearlings for the feedlot. This begins with movement of the animals from their farm source to the feedlot. The ideal situation would be to avoid public salesyards and move the cattle directly from the ranch to the feedlot. This avoids the stress of handling, overcrowding, temporary starvation, exposure to aerosol infection from other cattle, and the unnecessary delays associated with buying and selling cattle. However, large intensified feedlots are unable to buy cattle directly from the herd of origin according to their needs at a particular time and thus inevitably purchase large groups of cattle of different backgrounds. This has necessitated the development of conditioning procedures or processing procedures in which, after arrival, the cattle are individually identified, injected with a mixture of vitamins A, D, and E, treated with a residual insecticide, perhaps given an anthelmintic, injected with a long-acting antimicrobial and vaccinated for clostridial and respiratory diseases. The issue of whether the cattle should be processed immediately after arrival or after a rest period of 2–3 weeks remains unresolved because there are few data to support one time over the other. However, the feedlot industry feels that processing immediately after arrival is most economical.

Feeding newly arrived cattle
The feeding and nutritional status of newly arrived cattle is important but there are few scientific data to formulate a sound economic feeding program that will promote rapid recovery from shipping stress. Good results can be achieved when stressed calves are fed a receiving ration consisting of 50–75% concentrate with good-quality hay in a total mixed ration for the 2–3 weeks until the cattle have become adapted to their new environment.

Vaccines
General comments
Pasturella vaccines and respiratory viral vaccines have been used extensively in an attempt to control pneumonic pasteurellosis in cattle. A review of the literature in 1997 on the efficacy of the vaccines available for the control of bovine respiratory disease concluded that there were few documented data to support the use of vaccines against respiratory disease under feedlot conditions. Since that time progress has been made in understanding immunity to pneumonic pasteurellosis, and some vaccines with varying degrees of efficacy have been developed. The development of experimental models to reproduce the disease with Pasteurella haemolytica has provided a challenge method for evaluating the efficacy of the vaccines.

Various commercial vaccines induce differences in the rapidity and intensity of serum antibody responses to Pasteurella haemolytica whole cells and leukotoxins. However, well-controlled field trials are necessary to compare efficacy under naturally occurring conditions.

Pasteurella vaccines
Based on the immunological and microbiological observations of both the naturally occurring and experimental disease it appears that immunization of cattle is possible. Calves that recover from experimentally induced pneumonic pasteurellosis possess increased resistance to subsequent experimental challenge. Cattle that have recovered from the natural disease are resistant to the disease. High levels of naturally acquired antibody to Pasteurella haemolytica leukotoxin have been associated with protection against the disease.

The challenge in the development of an efficacious vaccine against pneumonic pasteurellosis has been to determine the most effective protective antigens of the organism.

Several different Pasteurella vaccines have been developed based on the virulence factors, including exotoxic leukotoxin, lipopolysaccharide and endotoxic activity, capsular polysaccharide, and iron-regulated outer membrane proteins. Each of the vaccines produced may provide some protection against experimental and naturally occurring disease but none provides a high degree of protection.

Several outer membrane proteins of P. multocida type A3, which occasionally causes a severe bronchopneumonia in cattle, may be important for immunity to the organism. A vaccine made of the outer membrane protein fraction of Pasteurella haemolytica induces a protective response in calves against intratracheal challenge exposure with the homologous serovar. A tissue-culture-derived Pasteurella haemolytica serotype 1 vaccine elicits a serotype-specific inhibition of nasal and tonsillar colonization by the homologous serotype under field conditions.

Calves naturally exposed to Pasteurella haemolytica or vaccinated subcutaneously or intradermally with the whole cell live organisms are resistant to experimental challenge and develop antibodies to all surface antigens and leukotoxin antibody titer. This supports the hypothesis that protection against experimental challenge with Pasteurella haemolytica may require an immune response to leukotoxin. Cattle that have died from pneumonic pasteurellosis have lower leukotoxin neutralizing activity in their sera than cattle from the same group that died from other causes. This important observation was followed by vaccination of calves with a leukotoxic culture supernatant from Pasteurella haemolytica, which provided some protection against experimental challenge with Pasteurella haemolytica AI. One vaccination of cattle with a Pasteurella haemolytica leukotoxin extract vaccine was as effective in enhancing protection against experimental challenge as two vaccinations.

The use of modified-live Pasteurella haemolytica and P. multocida vaccine in dairy calves between 14 and 20 days of age was effective in increasing titers of antibodies against Pasteurella haemolytica but did not improve calf health or performance. Vaccination of colostrum-deprived calves at 2 and 4 weeks of age with a Pasteurella haemolytica AI culture supernatant vaccine resulted in high titers of IgM antibodies to capsular polysaccharide...
within 1 week of vaccination. All vaccinated calves seroconverted with leukotoxin-neutralizing antibodies but peak antibody levels were low. Following experimental challenge, vaccinated calves had considerable lung injury but survival rate, clinical scores, and amount of lung involvement were better than those of control calves.

Leukotoxin extract vaccine
Resistance to pneumonic pasteurellosis correlates well with high serum antibody levels to various antigens of *M. haemolytica*, such as leukotoxin and various capsular antigens, and has led to the use of these components in the development of vaccines. High leukotoxin-neutralizing antibody titers induced by natural infections have been associated with reduced susceptibility to pneumonic pasteurellosis. Vaccination of calves with a leukotoxin culture supernatant from pathogenic *M. haemolytica* provides some protection against experimental challenge with the organism.

The efficacy of the leukotoxin extract vaccine has been evaluated in clinical field trials against naturally occurring bovine respiratory disease in weaned beef calves 6–8 months of age entering feedlots in Ontario and Alberta. In an initial field trial in Alberta, auction-market-derived calves were given two doses of the vaccine within 1–5 days of arrival. Mortality from all causes was significantly lower in vaccinated calves (4.2% vs 2.1%) and mortality due to fibrinous pneumonia was lower (2.2% vs 1.1%). In a trial in Ontario feedlots, recently shipped non-preconditioned calves were vaccinated within 24 hours after arrival. The vaccine resulted in a slight decrease in morbidity, slight improvement in treatment response rates and a reduction in relapse rates. When the vaccine was combined with a modified live virus vaccine containing the IBR and PI-3 viruses, the mortality rate increased. However, the number of calves in each group was insufficient to adequately evaluate the differences. In another trial in Alberta, calves were assigned to one of four groups:

- Vaccinated on the ranch of origin
- 3 weeks prior to shipment to the feedlot
- Vaccinated only on arrival at the feedlot
- Vaccinated at both locations
- Not vaccinated at either location

The vaccine did not result in a change in morbidity or weight gain. Total mortality rates were increased significantly, and mortality rates from respiratory disease tended to be increased in ranch calves vaccinated at the ranch. However, calves moved directly from ranches to feedlots, regardless of vaccination status, had lower morbidity and mortality, and better weight gains, than calves purchased from auction markets. In summary, there were no major benefits from vaccination. One of the problems may be the timing of the vaccination. Ideally, calves should be vaccinated at least 2 weeks prior to arrival at the feedlot; this is consistent with the temporal design of the laboratory studies, in which the first vaccination was given 42–51 days before challenge.

A single vaccination of a *M. haemolytica* bacterin-toxoid given to calves on arrival in the feedlot reduced overall crude mortality but there were no differences between vaccinates and nonvaccinates in bovine respiratory disease-specific mortality, morbidity, and/or average daily gain. Vaccination of seronegative persistently infected BVDV calves with a *M. haemolytica* bacterin-toxoid does not result in increased *M. haemolytica* antibodies compared to BVDV negative calves receiving the same vaccine.

Vaccination of feedlot cattle prior to transport to the feedlot with a *M. haemolytica* bacterin-toxoid elicited an antibody response but did not have any effect on *M. haemolytica* colonization of the nasopharynx. Florfenicol given on arrival reduced the incidence of respiratory disease, delayed the interval before onset of disease and reduced the incidence of colonization of the nasopharynx by *M. haemolytica*.

Vaccination of calves after arrival in the feedlot with a genetically attenuated leukotoxin of *M. haemolytica* combined with bacterial extracts of *M. haemolytica* and *H. somni* reduced morbidity due to bovine respiratory disease. The same vaccine, along with a modified-live BRSV vaccine, has been used to aid in the control of enzootic pneumonia in beef calves vaccinated at 3–5 weeks of age. Vaccination of feedlot calves after arrival with the genetically attenuated leukotoxin of *M. haemolytica* combined with bacterial extracts of *M. haemolytica* alone reduced the risk of UBRD.

Whole cell vaccine
Experimental vaccination of calves with live *M. haemolytica* or *P. multocida* by aerosol or subcutaneous route effectively reduces the severity of subsequent experimental disease. Vaccinated calves develop high serum antibody titers to the somatic antigens of the homologous organism.

Passive immunity to *Mannheimia haemolytica*
Vaccination of pregnant dairy cows at 6 and 3 weeks before parturition with a leukotoxin extract vaccine induced leukotoxin-neutralizing serum antibody titers in the cows, increased titers in colostrum and increased passive leukotoxin-colostal antibody titers in the calves. Vaccination was also associated with increased indirect agglutinating serum antibody titers in the cows. The protective effect of the antibodies against naturally occurring disease in the calves was not determined.

Vaccination of beef cows with a combined genetically attenuated leukotoxin *M. haemolytica* vaccine and a *H. somni* vaccine once at 4 weeks prepartum increases passive antibody titers to both organisms in their calves. Double vaccination of the calves with pre-existing maternal antibodies at 1 and 2 months of age will increase antibody titers to both organisms until 6 months of age. Vaccination of beef calves with low levels of pre-existing antibody at 3 and 4 months of age will increase antibody titers to *H. somni* until 6 months of age and to *M. haemolytica* until 5 months of age. Thus, prepartum vaccination may be an effective measure for the control of pneumonia in calves under 2 months of age, and vaccination of the calves at 3 and 4 months of age may provide additional protection until the calves are 6 months of age.

Evaluation of efficacy of *Mannheimia haemolytica* vaccines

**Meta-analysis of the published literature**

On the efficacy of the various vaccines against pneumonic pasteurellosis of cattle indicates that culture supernatants and/or potassium-thiocyanate-extracted outer membrane protein vaccines perform as well as live vaccines. Live vaccines are considered to be the best in terms of protective immunity induced against pneumonic pasteurellosis because they replicate at the site of injection and produce the important immunogens that stimulate a protective immune response. However, live vaccines are associated with side-effects such as fever, local abscessation, and lameness.

**Commercial vaccines have been evaluated by measuring antibodies**

- 4–6-week-old calves vaccinated against leukotoxin, capsular polysaccharide, whole cell antigens, and iron-regulated outer membrane proteins, A bacterin-toxoid, a leukotoxin culture supernatant, a modified-live *M. haemolytica* and *P. multocida* vaccine, and an outer membrane extract of the organism were all evaluated. All vaccines induced antibodies to the antigens but there were wide variations between the vaccines: some vaccines demonstrated little if any antibody to leukotoxin or outer membrane proteins. The highest leukotoxin antibody titers of the vaccines were observed after 4 weeks.
titer did not reach its peak until 14 days after the booster dose of vaccine, which suggests that a second dose of vaccine is necessary for protection.

The efficacy of three commercial vaccines was evaluated against experimental pneumatic pasteurellosis. Promiscuity was identified by assessment of clinical scores and lung lesions after endobronchial challenge with virulent M. haemolytica. There was significant correlation between lung and serum antibody levels against leukotoxin, capsular polysaccharide and outer membrane proteins. The vaccines did not provide optimal protection but the bacterin-toxoid vaccine was superior to the others. The culture supernatant containing leukotoxin, lipopolysaccharide, and capsular polysaccharide provided the best protection against experimental disease compared to a sodium salicylate extract containing outer membrane proteins, lipopolysaccharide, and capsular polysaccharide, and a combination of the above two. Leukotoxin is an important virulence factor in the disease and its use in vaccines provides significant protection. Muramyl dipeptide analogs may increase the humoral and protective response of calves to capsular polysaccharide.

Adverse vaccine reactions

Some adverse reactions are associated with live vaccines. Systemic infection due to M. haemolytica occurred 2–18 days following vaccination with an avirulent live culture of M. haemolytica. Lesions included injection site inflammation, purulent meningitis, and polyarthritis. Abscess formation at injection sites after vaccination with modified live M. haemolytica vaccines is also possible. The purified capsular polysaccharide of M. haemolytica used in combination with other antigens did not provide protection but rather caused a high incidence of anaphylaxis.

Viral vaccines

Because prior infection of the respiratory tract with either IBRV or PI-3V may predispose to pneumatic pasteurellosis, the vaccination of beef calves 2–3 weeks before weaning and feedlot cattle 2 weeks before shipment to a feedlot has been recommended as part of a preconditioning program. Vaccination of calves at 3–6 months of age with an intranasal modified live IBR and PI-3V vaccine provides protection against experimental pneumatic pasteurellosis induced by aerosol challenge with IBR followed 4 days later by an aerosol of M. haemolytica. Using this principle of control it would be necessary to vaccinate the calves at least 2 weeks before they are weaned, stressed, or transported to a feedlot on arrival with modified live virus vaccines, while commonly done, may be associated with increased mortality. The development of viral vaccines that contain viral glycoproteins and inactivated whole-virus IBRV, which are immunogenic but do not cause disease, may show some promise.

Vaccination programs

Feedlot cattle

Under ideal conditions, feedlot cattle should be vaccinated twice at a 14-day interval with the M. haemolytica bacterial extract and genetically attenuated leukotoxin vaccine, with the second dose at least 14 days before arrival in the feedlot. However, in commercial feedlots, cattle are usually vaccinated only once after arrival. The second dose is not given because most cases of shipping fever occur within 2 weeks after arrival. Experimentally, one vaccination is as effective as two vaccinations. The presence of the organism as a natural commensal in the upper respiratory tract can efficiently prime the animal and allow it to respond in an anamnestic mode to only one vaccination.

Beef breeding herds

The breeding herd is vaccinated annually with the M. haemolytica bacterial extract and genetically attenuated leukotoxin vaccine at 4 and 7 weeks prepartum to boost specific colostal antibody levels.

Nursing beef calves

Calves are vaccinated at 3–4 months of age, twice, at a 14-day interval with the M. haemolytica bacterial extract and genetically attenuated leukotoxin vaccine.

Dairy cattle herds

Pregnant dairy cattle are vaccinated with the M. haemolytica bacterial extract and genetically attenuated leukotoxin vaccine at 4 and 7 weeks prepartum to boost specific colostal antibody levels. Dairy calves are vaccinated beginning at 4–6 months of age as part of a calfood vaccination program.

Chemoprophylaxis

Antimicrobials are used for the control of pneumatic pasteurellosis, particularly in calves that have just been introduced into a feedlot. Vaccination on arrival with modified live virus vaccines, while commonly done, may be associated with increased mortality. The development of viral vaccines that contain viral glycoproteins and inactivated whole-virus IBRV, which are immunogenic but do not cause disease, may show some promise.

Mass medication of individual animals

The early onset of pneumatic pasteurellosis in cattle within a few days after arrival in the feedlot requires consideration of mass medication of all animals in a group as part of a health management program. Field trials indicate that administration of antimicrobials to calves at varying times on arrival in the feedlot can reduce subsequent morbidity and mortality from respiratory disease. The administration of antimicrobials to high-risk calves immediately after arrival is particularly effective under commercial feedlot conditions. Meta-analysis of the literature on mass medication for bovine respiratory disease indicates that prophylactic parenteral mass medication of calves with long-acting oxytetracycline or tilmicosin on arrival at the feedlot will reduce bovine respiratory disease morbidity rates.

The injection of trimethoprim-sulfadiazine or oxytetracyclines on arrival reduced morbidity and mortality from respiratory disease in high-risk calves. The administration of a long-acting preparation of oxytetracycline at a dose rate of 20 mg/kg BW intramuscularly to feedlot cattle on arrival can reduce the morbidity and mortality from respiratory disease. Both the intramuscular and subcutaneous administration of oxytetracycline formulation are comparable to the intramuscular administration of currently available oxytetracycline formulation. The efficacy of three commercial vaccines is also possible.75

The administration of a long-acting preparation of oxytetracycline at a dose rate of 20 mg/kg BW intramuscularly to feedlot cattle on arrival can reduce the morbidity and mortality from respiratory disease. Both the intramuscular and subcutaneous administration of oxytetracycline formulation are comparable to the intramuscular administration of currently available oxytetracycline formulations after arrival in the feedlot. Tilmicosin, at 10 mg/kg BW subcutaneously, given to calves immediately after arrival significantly reduced the treatment rate for bovine respiratory disease during the first 5 days as well as during the first month of the feeding period. The relapse rate and the treatment rate for all diseases during the first month were also reduced. The administration of tilmicosin to calves either upon arrival at the feedlot, or 3 days later, reduced the treatment rate for respiratory disease in the first 30 days. The average daily gain was also improved in the treated group compared to the controls, and the feed conversion efficiency over the first 60 days of the feeding period was superior in the medicated group compared to the nonmedicated animals.

Mass medication of feed and water supplies

Medication of the feed and water supplies has given variable results because of the difficulties in obtaining adequate levels of antimicrobials in those cattle that most need them. In normal weaned beef calves 6–8 months of age blood levels of sulfamethazine of 5 mg/L or greater can be achieved in 15–24 hours by providing medicated water at a dose rate of approximately 150 mg/kg BW; at 75 mg/kg BW the same blood levels are achieved by 72–84 hours. A standard recommendation is to provide 150 mg/kg BW for the first 24 hours and reduce the level to 75 mg/kg BW for the duration of the medication period, which may last 5–10 days. A feed additive containing 700 mg/head of chlortetracycline and sulfamethazine from the day of arrival at the feedlot to day 56 of the feeding period improved daily gain and feed conversion.
PART 2 SPECIAL MEDICINE . Chapter 1 8: Diseases associated with bacteria

A single intramuscular injection of 10 mg/kg tilmicosin or 20 mg/kg oxytetracycline is effective in preventing disease.2

P. multocida is a rare cause of septecmic disease in neonatal lambs but can occur with a high morbidity and high case fatality rate.3 Clinically, it presents with a syndrome resembling watery mouth with marked salivation, abdominal distension and a short clinical course. On post-mortem examination there is excess peritoneal and pleural pericardial fluid. Prophylactic long-acting tetracycline at a dose of 100 mg per lamb has prevented further cases.

**Matstis**

M. haemolytica is recorded as a major cause of mastitis in ewes in Britain. It has been isolated from the udder of 20% of ewes with subclinical mastitis and from 40% of cases of acute mastitis.4 A variety of typed and untyped strains within biotype A are isolated and serotype A2 is commonly isolated from acute mastitis. The epidemiology of the disease is unclear. Infection may occur from the organism on bedding5 but the source of infection is more probably from the nose and mouth of the suckling lamb, which is supported by the observation that the prevalence of mastitis associated with this organism is less in dairy sheep than in conventional flocks.6 Experimental challenge studies show that strains vary in their pathogenicity for the udder,6

**Pneumonic pasteurellosis affecting wildlife**

Pasturella and Mannheimia spp. have been isolated from a number of different species of wildlife but there has been particular concern with outbreaks of acute fatal pneumonic pasteurellosis that have occurred in Rocky Mountain and desert bighorn sheep (Ovis canadensis) following commingling with domestic sheep or feral goats.7 M. haemolytica, P. trehalosi, and P. multocida have been isolated. P. trehalosi serotypes are carried in the tonsils of healthy bighorn sheep2 but bighorn sheep are believed to be particularly susceptible to pathogenic biotype A strains acquired as a result of commingling with domestic sheep on range coupled with the stress of high densities and food shortage.7,8,9 This association has raised environmentalists concerns for practices of communal grazing of domestic sheep with wildlife species. As with sheep, disease associated with these bacterial species in wildlife has not been prevented by vaccination with current vaccines.11

Organism carried in oropharynx and tonsils of healthy sheep and goats. Carrier prevalence rate increases in late spring/early summer and again in early autumn, which coincides with an increased prevalence of disease. Disease occurs in ewes and young lambs in late spring and early summer and feeder lambs late summer. Commonly there is a history of stress. In pastured sheep outbreaks often associated with changes in climate or management. Outbreaks in housed sheep associated with poor ventilation.

**Clinical findings**

Rapid onset and short course. Outbreaks often heralded by sudden death. Fever, cough, respiratory distress, dyspnea. Sheep that recover have persisting ill health.

**Necropsy findings**

Fibrinous pleuritis, pericarditis, and bronchopneumonia

**Diagnostic confirmation**

Lesions found on necropsy. Culture, biotyping, and serotyping.

**Treatment**

Antibiotics

**Control**

**ETIOLOGY**

Pneumonic pasteurellosis in sheep and goats is associated with biotype A of Mannheimia (Pasteurella) haemolytica. Serotype A2 is the most prevalent serotype isolated from pneumonic lungs in both sheep and goats. Less common but important serotypes in sheep are A1, A6 to A9, A11, and A12, and in goats A1 and A6, although there is some regional variation.12 Some experimental challenge studies suggest that there is a difference in virulence between serotypes, with serotypes A1, A2, A7, and A9 having greater virulence. Untypable serotypes can account for approximately 10% of isolates from pneumonic lungs.

Infection with PI-3V or Bordetella parapertussis may predispose to pneumonic pasteurellosis.7

M. haemolytica is a normal inhabitant of the upper respiratory tract of sheep. Colonization of the nasopharynx and the tonsils occurs very shortly following birth, mainly from the ewe but also from the environment, and carriage persists through adult life. M. haemolytica has been isolated from 95% of the tonsils and 64–75% of nasopharyngeal swabs from normal adult sheep.13 In healthy flocks there is considerable sheep-to-sheep variation in the biotype and serotype present in the nasopharynx and there are cyclical changes in carrier rate with time and changes in the predominant serotypes that are present. When compared to healthy flocks the prevalence of carriers is higher in flocks that are experiencing disease and there is more decisive prominence of a particular serotype. The carrier prevalence rate also increases in late spring and early summer and again in early fall, which coincides with an increased prevalence of disease.

M. haemolytica is also present on grass and in water in grazing areas and in the bedding of sheep pens; survival in these environments is prolonged in cooler, wet conditions.9

**EPIDEMIOLOGY**

**Occurrence**

The disease occurs in sheep of all ages and causes losses in sheep in most parts of the world, through both death and depression of weight gain. The seasonal prevalence varies regionally. In the northern hemisphere, outbreaks, as opposed to sporadic disease, are more prevalent in the late spring and early summer. In contrast, in New Zealand and Australia the disease is more prevalent in the late summer and fall, occurring in lambs associated with mustering or transport in hot weather.10

Lambs are most susceptible during the first few months of life and ewes are most susceptible at lambing,4 Outbreaks in lambs can have attack rates up to 40% and a population mortality up to 5%. Both ewes and lambs can be affected in the same outbreak. Outbreaks often start with sudden death in lambs from septicaemia pasteurellosis and progress to pneumonic pasteurellosis in the ewes and also in the lambs as they get older. The loss of 400 of 1200 ewes from this disease over a 3-year period is recorded11 and a mean flock population mortality of 24% has been calculated from 450 outbreaks in Britain.4

In housed lambs the majority of deaths occur over a 2-week period, 3–6 weeks after entry,12 death losses in feeder and housed lambs are usually of the order of 5%,10 but may be as high as 20%.

High mortality has occurred in goats kept in confined quarters after collection from a number of centers.

**Experimental reproduction**

Pneumonic pasteurellosis can be experimentally reproduced by challenge of specific-pathogen-free lambs with aerosols of M. haemolytica, either given alone or...
preceded by PI-3V or *B. parapertussis* challenge and by intratracheal inoculation.

**Environmental and pathogen risk factors**

In *sheep at pasture*, the disease tends to spread slowly and the population mortality rate is lower than in feeder lambs maintained in small areas. Outbreaks in flocks at pasture are frequently associated with changes in climate or management and deleterious changes in environment. In range sheep, confinement for shearing, mating or supplementary feeding may precipitate an outbreak, and severe parasitism or rain and wind chill, exposure to bad weather or sudden change in weather may also increase susceptibility, with deaths starting within 2 weeks of the stress factor.

In *housed sheep*, risk factors for disease include conminigation of animals from different sources, taking sheep to shows, drafty or poorly ventilated barns, transport and malnutrition.  

Feedlot dust contains significant endotoxin and it has been postulated that inhalation of dust may be a predisposing factor in feedlot sheep. However, an experimental challenge study found no effect.

PI-3V appears to be an important predisposing factor to pneumonic pasteurellosis in some outbreaks, based on serological evidence of concurrent infection with PI-3V during outbreaks of pasteurellosis in sheep. Adenovirus may also predispose to naturally occurring and experimentally produced pneumonic pasteurellosis.

**PATHOGENESIS**

The development of pneumonic pasteurellosis in sheep and goats is in general the same as in pneumonic pasteurellosis of cattle. *M. haemolytica* is a primary pathogen in very young lambs but older lambs are more resistant and predisposing factors are required for the production of disease. Infection with PI-3V impairs the bactericidal activity of ovine neutrophils and the clearance of *M. haemolytica* by the ovine lung. PI-3V has been incriminated in some outbreaks. Experimental infection of specific-pathogen-free lambs with this virus, followed 4 or 7 days later by infection with *M. haemolytica*, results in pneumonic pasteurellosis that resembles the naturally occurring disease.

Organisms such as *Mycoplasma ovispneumoniae* and *B. parapertussis* colonize the lower respiratory tract in large numbers and attach to cilia, reducing pulmonary clearance of other organisms, which may explain the predisposition of chronic progressive pneumonia to secondary infection with *M. haemolytica* under stress situations.

*M. haemolytica* itself has cell-wall-associated components that may help it to become established during an infection and that are putative virulence determinants. It produces a leukotoxin (cytotoxin) that is considered to be an important virulence factor in the pathogenesis of ovine pneumonic pasteurellosis and promotes bacterial proliferation by killing or incapacitating ruminant neutrophils and pulmonary macrophages. It is a member of the RTX family of Gram-negative bacterial pore-forming cytotoxins. It is specific for ruminant lymphoid cells. Leukotoxin binding occurs via a high-affinity species-specific mechanism and beta-2 integrins are the putative leukotoxin receptor on leukocytes.

Two other components, *capsular polysaccharide* and *lipopolysaccharide*, attach to alveolar and bronchial epithelium. Capsular polysaccharide precipitates pulmonary surfactant and *M. haemolytica* may attach to this surfactant layer in the alveolus by the lectin reaction of its capsular polysaccharide, thus promoting its establishment and colonization in the lung.

**Intraspecific variation** in virulence determinants may be responsible for observed differences in host specificity. As in cattle, the endotoxic activities of the bacterial lipopolysaccharide are believed to be critical to the development of the pulmonary lesions, and lipopolysaccharide deposited directly into the lung produces lesions similar to these seen in the lung of natural cases.

In New Zealand, slaughterhouse data consistently show a higher prevalence of lesions of pleurisy and pneumonia in sheep from the warmer areas of the country and this, coupled with the late summer occurrence of clinical disease, suggests heat stress as a predisposing factor, possibly acting through the by-passing of nasal defense mechanisms by open-mouthed breathing.

**CLINICAL FINDINGS**

Outbreaks often commence with sudden deaths in the absence of premonitory clinical signs. In groups of lambs this occurrence of sudden death without prior illness may continue throughout the outbreak but some older sheep will show signs of respiratory distress, which can be accentuated by driving. As the outbreak progresses, respiratory involvement becomes more evident, signs including dyspnea, slight frothing at the mouth, cough, and nasal discharge. Affected sheep have fever from 40.4–42.0°C (105–107°F) and are depressed and anorectic. In more chronic cases an increase in intensity of air-flow sounds with an increase in pitch is heard over the area of the bronchial hilus, often with fluid sounds. Death may occur as soon as 12 hours after the first signs of illness but the course in most cases is about 3 days. Sheep that recover have evidence of chronic pneumonia and are often culled because of persisting ill-health and poor thrift. In cases produced experimentally, arthritis, pericarditis, and meningitis occur in lambs that survive the acute stages of the disease, but these are not often observed in natural cases.

**CLINICAL PATHOLOGY**

Most outbreaks are heralded by dead sheep and the diagnosis is established by postmortem examination. There is little information concerning the clinical pathology or the cellular findings in tracheobronchial aspirates in natural case. The organism can survive considerable periods in tracheobronchial washings. Nasal swabs for culture are of little value because of the high carriage rate by healthy sheep of the organism in the nasopharynx.

**NECROPSY FINDINGS**

With pneumonic pasteurellosis, petechial and ecchymotic hemorrhages are present throughout the body but the salient findings are in the thoracic cavity. In sheep that have died from peracute pneumonic pasteurellosis there is a greenish gelatinous exudate over the pericardium and large quantities of straw-colored pleural exudate. The lungs are enlarged, edematous, and hemorrhagic. With less acute cases there is consolidation of the lung, usually the apical and cardiac lobes but occasionally in the diaphragmatic lobe. The affected lung is solid and clearly demarcated. Histologically, there is diffuse alveolar necrosis, edema of interlobular septa, and sloughing of bronchial mucosa, and in sheep that survive the peracute phase of the disease there are so-called ‘oat cells’ in zones surrounding the necrotic alveoli. The organism can be cultured in large numbers in lung lesions and exudates.

**Samples for confirmation of diagnosis**

- Bacteriology – lung, bronchial node, retropharyngeal node, spleen (CULT)
- Histology – formalin-fixed lung, liver, kidney (LM)

**DIFFERENTIAL DIAGNOSES**

When deaths occur in lambs without prior clinical illness the primary differentials are:

- Septicemia associated with *Histophilus somni* (formerly *Haemophilus somnus*)
- Enterotoxemia associated with *Clostridium perfringens* type D
- Other causes of sudden death

Parasitic pneumonia, jaagsiekte, chronic nonprogressive pneumonia, and chronic progressive pneumonia (maedi) are the common chronic pulmonary conditions of sheep, but these should not be confused with pasteurellosis because of their longer course and distinctive features.
against experimental challenge with *H. haemolytica* in sheep and goats, they are not always effective in natural outbreaks and several studies show limited or no protection against natural disease in the field. This may be because the relevant serotype is not in the vaccine formulation. There have been few controlled trial studies of vaccination. Vaccines containing concentrated components of organisms such as outer membrane proteins show potential for cross-serotype protection with experimental infections but remain to be proved in the field.

Vaccines containing various serotypes of *M. haemolytica* stimulate antibody production in pregnant ewes and the lambs receive colostral antibody, which does interfere with the production of antibody by the lambs if they are vaccinated at an early age.

Another approach to control is the vaccination of lambs with Pl-3V vaccines in addition to *Pasteurella* vaccination in an attempt to immunize lambs against challenge exposure with both this virus and *H. haemolytica*. The experimental vaccination of specific-pathogen-free lambs with an inactivated Pl-3V vaccine provides protection against the combined effect of an experimental challenge with Pl-3V and *H. haemolytica*, and field reports suggest that this vaccination is of value.

**CONTROL**

Environmental and managerial factors that may precipitate outbreaks of the disease should be controlled where possible.

**Antibiotics**

The use of long-acting tetracycline in the face of an outbreak is a common approach to control. At-risk animals are given the drug intramuscularly at a dose rate of 20 mg/kg BW. The treatment may be repeated at 4-day intervals. A controlled field trial of this procedure has shown it to be efficacious. The feeding of broad-spectrum antibiotics, especially tetracyclines, to lambs in feedlots is a common method of preventing pneumonia in recently weaned lambs. However, there is no documented evidence of its efficiency.

**Vaccination**

There has been considerable activity in the development of vaccines for the control of pasteurellosis in sheep and goats; however, the development of an effective vaccine has proved elusive. Early studies showed that sheep that had recovered from infection were resistant to subsequent homologous challenge. Also, immune serum will protect against experimental homologous lambs. Because *M. haemolytica* A2 is the most common isolate from pneumatic lungs of sheep and goats throughout the world, most research on vaccines for sheep and goats has focused on incorporating either a suitable isolate of *M. haemolytica* A2 or suitable antigens extracted from the serotype. Different antigen preparations have been used and, whereas most studies have shown that vaccination can give protection against homologous challenge, there is variable protection against challenge with other serotypes of *M. haemolytica*. The approach has thus been to incorporate other serotypes in the vaccine, usually the ones that are common in the region of vaccine manufacture. However, despite the fact that vaccines that incorporate different serotypes are marketed, they do not always provide satisfactory control of pasteurellosis.

**DISEASES ASSOCIATED WITH PASTEURELLA SPECIES**

5. Appleyard WT, Gilmour NJL. Vet Rec 1990; 126:231.

**SEPTICEMIC PASTEURELLOSIS IN WEANED SHEEP**

**Etiology**

*Pasteurella multocida* (Pasteurella haemolytica biotype T)

**Epidemiology**

*P. multocida* is carried in oropharynx and tonsils of healthy sheep and goats. Carrier prevalence rate increases in late spring/early summer and again in early autumn, which coincides with an increased prevalence of disease. Septicemic pasteurellosis in weaned lambs commonly follows stress such as transport, marketing, shearing, coupled with a change to better feed.

**Clinical findings**

Clinical disease seldom seen, as clinical course is very short. Affected sheep are dull, rapidly become prostrate and toxemic with frothy bloody nasal discharge in the terminal stages. Necropsy findings include congestion and edema. Necrotic ulcers of abomasum. Multifocal hepatitis.

**Diagnostic confirmation**

Necropsy lesions. Culture, biotyping, and serotyping are recommended.

**Treatment**

**Antibiotics**

Long-acting tetracyclines in the face of an outbreak. Avoidance of stress. Vaccination may be of value.

**ETIOLOGY**

The disease is associated with septicemic infection with *Pasteurella multocida*, which occurs most commonly following stress. *P. multocida* is a common inhabitant in the upper respiratory tract and tonsils of healthy sheep. The organism was previously known as *P. haemolytica* biotype T and all four serotypes within this biotype have been incriminated in the disease.

**EPIDEMIOLOGY**

**Occurrence**

This is an important disease in regions of Britain; it occurs in Europe and the USA. While recorded as occurring in Australia or New Zealand it is not a significant disease in these countries. The disease occurs predominantly in weaned lambs 5–12 months of age. It occurs following a form of stress such as transport, marketing, or shearing, or coupled with a change to better feed.
movement to better feed, which is often to turnips, rape, or alfalfa and crop aftermath grazing. In Britain it is a disease of sheep moved from hill and upland farms to lowland farms for fattening.

In North America it is a disease of feedlot lambs and occurs following a change from roughage to concentrate feeding.

In affected groups a population mortality up to 9% is recorded and in some areas septisemic pasteurellosis is the most common cause of death in lambs of this age group.

Experimental reproduction

The disease has been reproduced by oral inoculation coupled either with rapid change in feed from cutaneous hemorrhages over the neck and thorax are common. The trachea and thorax are congested and edematous, and there are subpleural ecchymoses, but there are limited or no protection against experimental infection. Although an embolic pneumonia from which the organism to other internal organs.

When deaths occur in lambs without prior illness the primary differentials are:

- Septicemia associated with Histophilus somni (formerly Haemophilus somni)
- Enterotoxemia associated with Clostridium perfringens type D
- White muscle disease
- Toxidrome

TREATMENT

Where possible, treatment should be based on sensitivity testing of the isolate associated with the outbreak. Isolates of Pasteurella multocida are often resistant to penicillin and oxytetracyclines. Florfenicol or cefotaxim should be considered if the sensitivity is unknown. The whole group should be treated prophylactically by injection or, if there is an appropriate antimicrobial, in the feed or water.

CONTROL

Environmental and managerial factors that may precipitate outbreaks of the disease should be controlled where possible.

Vaccination

Immune serum will protect against experimental challenge in specific-pathogen-free lambs. However, despite the fact that vaccines have been developed that engender protection against experimental challenge, they are not always effective in natural outbreaks and several studies show limited or no protection against natural disease in the field.

REFERENCES

8. Wells PW et al. Vet Rec 1984; 114:266

PASTEURELLOSIS OF SWINE

Pasturella multocida is an important pathogen of pigs. Toxicogenic strains, in conjunction with Bordetella bronchiseptica, are recognized as the etiological agents of atrophic rhinitis described under that heading. Pneumonic pasteurellosis and septisemic pasteurellosis are also manifestations of infection with Pasteurella multocida in pigs. It has recently been shown that Pasteurella multocida capsular type A can cause not only septisemia in growing pigs but also septicemia and arthritis as well as being associated with the presence of skin lesions in sporadic cases of porcine dermatitis and nephropathy syndrome.

PATHOGENESIS

Pasteurella multocida colonizes the tonsil and in affected sheep necrotic lesions are consistently found in the tonsils and the pharyngeal mucosa and sometimes in the abomasal mucosa. It is postulated that bacteria invade from these lesions and enter the bloodstream via venous and lymphatic routes to produce embolic pneumonia with hematogenous spread of the organism to other internal organs. The organism proliferates in these areas to produce a fatal bacterial endotoxemia.

CLINICAL FINDINGS

Septisemic pasteurellosis

Clinical disease is seldom seen as the clinical course is often less than 6 hours and affected sheep are found dead. Affected sheep are dull, rapidly become prostrate, are toxemic, and may have a frothy bloody nasal discharge in the terminal stages.

CLINICAL PATHOLOGY

Most outbreaks are heralded by dead sheep and the diagnosis is established by the typical lesions at postmortem examination. There is little information concerning the clinical pathology. Nasal swabs for culture are of little value because of the high carriage rate in healthy sheep of the organism in the nasopharynx.

NECROPSY FINDINGS

The principal lesions are in the upper alimentary tract, thorax, and liver. Subcutaneous hemorrhages over the neck and thorax are common. The trachea and bronchi contain blood-stained froth, the lungs are congested and edematous, there are subpleural ecchymoses, but there is no pneumonia on gross examination, although an embolic pneumonia is evident histologically. The tonsils and pharyngeal lymph nodes are enlarged and there is ulceration and necrosis of the pharynx and esophagus. There is also hemorrhage, and small necrotic ulcers are present on the tips of the folds of the abomasal mucosa.

Histologically there is acute inflammation and emboli in small arterioles and capillaries. The organism can be isolated in large numbers from the tonsils, lungs, liver, and mucosal lesions of the pharynx and esophagus.

Samples for confirmation of diagnosis

- Bacteriology – lung, spleen (CULT)
- Histology – formalin-fixed lung, upper alimentary tract ulcers, liver, kidney (LM).

DIFFERENTIAL DIAGNOSIS

When deaths occur in lambs without prior illness the primary differentials are:

- Septicemia associated with Histophilus somni (formerly Haemophilus somni)
- Enterotoxemia associated with Clostridium perfringens type D
- White muscle disease
- Toxidrome

NPECNOIFIC PASTEURELLOSIS

ETIOLOGY

Pasteurella multocida is commonly isolated from the lungs of pigs with chronic pneumonia, purulent bronchopneumonia, and pleuritis. Isolates are predominantly capsular serotype A strains with some serotype D strains. It is possible to serotype Pasteurella multocida and of the 16 serotypes, serotypes 3 and 5 are the predominant isolates. In most herds there is a single isolate and this is usually A3. In a recent study 88% of the lung strains were type A (OMP strains 1:1, 2:1, 3:1, 5:1, and type 6:1). These authors suggest that the agent may be a primary pathogen with a relatively high degree of virulence and furthermore there has been a considerable transfer of capsular biosynthesis and toxA genes between the strains representing subpopulations of both type A and type D strains. It has recently been suggested that most Pasteurella multocida strains have the toxA gene. This is further evidence of a trend reported earlier, when it was suggested that there was widespread genetic diversity in the capsular type A strains and that a single clone might be more predominant in a particular pig population. For many years it was thought that toxigenic strains were not found in the lung but in three surveys 25–90% of the pneumonia strains were toxigenic. The largest and most recent study looked at 230 isolates from 250 pigs and found that 200 (88%) were A, 4% were D and 9% could not be identified. The toxA gene was found in 13%, of which 11%
belonged to A. 1% to D and 1% could not be typed. Serotype D strains were specifically associated with abscesses in the lung.

*P. multocida* is a common secondary infection in the lungs of pigs with enzootic pneumonia associated with *Mycoplasma hyopneumoniae*. The pneumatic lesions from which both organisms are recovered are more severe than those associated with *M. hyopneumoniae* alone.15 The organism is also a common secondary infection in pneumonia associated with *Actinobacillus pleuropneumoniae*.

**EPIDEMIOLOGY**

Although found in other species it is generally assumed that there is little interspecies transfer.

It is generally considered that *P. multocida* is not a primary pathogen of the lower respiratory tract and that its involvement in pneumonia is secondary to infection with other respiratory pathogens. A large-scale survey in Germany17 of 6560 postmortem examinations found that pneumonia was present in 24.4% of cases. In 49.3% of these *P. multocida* was found and with increasing age there was an increasing rate of recovery of *P. multocida*. Most of the lung cultures (54.2%) showed multiple infections. Pneumonic pasteurellosis cannot be reproduced by the intranasal or intratracheal challenge of healthy pigs with *P. multocida* but can be reproduced by challenge to pigs whose pulmonary clearance mechanisms have been compromised by infections with *Mycoplasma pneumoniae*,18 pseudorabies virus,19 or by anesthesia20 and also lungworms. Although atmospheric ammonia may predispose to nasal attachment of *P. multocida* type D it seems unlikely that this applies to pulmonary infection.1 It has been reproduced when nontoxicogenic strains are given repeatedly by intratracheal injection following *A. pleuropneumoniae* or *M. hyopneumoniae* infections.22 Strains vary in their ability to produce secondary pneumonia and pleuritis in these experimental models, suggesting the existence of specific pneumotropic and pleurotropic strains,19 which is supported by epidemiological studies that have found that a single strain predominates in problem herds.23 The organism is carried in the nasal cavity and tonsils of pigs, and carriage rates are higher in herds with a history of chronic respiratory disease.23

Transmission is by aerosol and more probably by direct nose-to-nose contact and hence by inhalation or ingestion. The bacterium has a short-term survival in aerosols, particularly of low humidity (less than 1 h), but survives for longer at high humidity and lower temperature. Heating to 60°C will kill it, but it can survive for up to 14 days in water, 6 days in slurry and up to 7 weeks in nasal washings at room temperature. There is always the feeling that the condition is most common under conditions of poor husbandry, notably overcrowding, and poor hygiene and where environmental stress is high. As a result it is often seen after transport, mixing or moving groups of pigs. The virulence mechanisms are not known but it is known that some may adhere to mucus and some have pili or fimbriae for attachment.24 Serotype A strains are resistant to phagocytosis, which has been attributed to the presence of capsular hyaluronic acid and might allow their colonization of lung lesions.9 Isolates from lung lesions are not invariably toxigenic. A recent study has shown that there is a change in the functional capabilities of the blood cells with oxygen radicle formation and phagocytosing neutrophils elevated after infection.25

**CLINICAL FINDINGS**

There is a possibility of a hyperacute condition in which the only sign is sudden death.

Pneumonic pasteurellosis is a common cause of sporadic cases of acute bronchopneumonia in grower-finisher pigs. Affected pigs have fever of up to 41°C (106°F), are anorectic and disinclined to move (lethargic), and show significant respiratory distress with labored respiration and increased lung sounds, often breathing through the mouth. Cyanosis may occur. Without treatment, death is common after a clinical course of 4–7 days. There is a marked tendency for the disease to become chronic, resulting in reduced weight gain and frequent relapses, and real recovery seldom occurs. Although pneumonic pasteurellosis is secondary to other underlying respiratory disease it can occur as an outbreak, spreading to affect several pigs within a group. The first indication of disease within a group and of an impending outbreak may be the finding of a pig dead with a purulent infection. In an intermediate stage there may be fever, coughing and poor growth rate for about 3–5 weeks before recovery. The disease may also exist in chronic form within pigs in a herd as part of the swine pneumonia complex with little evidence of overt clinical disease but with an effect on growth rate and food conversion efficiency.

**NECROPSY FINDINGS**

At necropsy the lesions are considered to be typical of what is normally called enzootic pneumonia – a chronic broncho-pneumonia with abscessation. Pleuritis is common and there may also be pericarditis. In some instances there may be cardiac congestion and the trachea may be full of frothy fluid. Experimental infections have caused between 15.3% and 39.4% of lung tissue to be affected with pneumonia.25 Histologically, the airways are filled with degenerate leukocytes but the overall lung pathology is often complicated by other pathogens. Pneumonic pasteurellosis cannot be manifested by a marked systemic or pulmonary involvement. Dyspnea is a prominent sign in Glasser’s disease but there is obvious arthritis at necropsy the disease is characterized by arthritis, a general serositis and meningitis.

**DIFFERENTIAL DIAGNOSIS**

The disease must be differentiated from other causes of respiratory disease in pigs. Enzootic pneumonia of pigs, unless accompanied by pasteurellosis, is not manifested by a marked systemic or pulmonary involvement.

Dyspnea is a prominent sign in Glasser’s disease but there is obvious arthritis at necropsy the disease is characterized by arthritis, a general serositis and meningitis.

Pleuropneumonia associated with *A. pleuropneumoniae* causes a severe pneumonia with rapid death, and differentiation from pasteurellosis is necessary at necropsy.

The septicemic and acute enteric forms of salmonellosis in pigs are often accompanied by pulmonary involvement but these are usually overshadowed by signs of septicaemia or enteritis. Chronic pasteurellosis has to be differentiated from lungworm infestations and ascariasis.

**TREATMENT**

The animals are usually severely ill so therefore treatment is firstly by parenteral injection and then by water medication and once they start to eat medication should continue with in-feed antibiotics.

Treatment is with antibiotics, commonly with tetracyclines. There is also a case for using cefotiofur, penicillin, streptomycin, trimethoprim/sulfonamides, ampicillin, spiramycin, and spectinomycin for 3–5 days. Tilmicosin and tildehexetron would also be suitable antibiotics. There is significant variation in the antibiotic sensitivity of isolates and the choice of antibiotic should be based on a sensitivity established for the organism in the UK. In a recent survey in the UK, 15% of
P. multocida isolates were resistant to tetracyclines and it was also reported that resistance to trimethoprim/sulfonamides, apramycin, and neomycin was found in some isolates. A German survey showed that 55% were resistant to sulfonamides.

**CONTROL**

Vaccination is ineffective, although autogenous vaccines have been produced that are effective (need to be certain that you have the strain causing the problem). Control depends on management of the risk factors, which are described under enzootic pneumonia of swine, since pasteurellosis is often secondary to that condition. In particular all-in-all-out management with vaccination for enzootic pneumonia is essential. Tiamulin at 40 ppm in the feed has also been used strategically at the time of stress, for example over mixing and moving.

**SEPTICEMIC PASTEURELLOSIS**

Septicemic disease with death occurring within 24 hours and without signs of pneumonia is occasionally observed in neonatal pigs. Septicemic disease is also recorded in India in association with infection with capsular serotype B.3,30 The disease occurs in all ages of pigs including adults and is manifest with fever, dyspnea, and edema of the throat and lower jaw. A population mortality of 40% in a group of pigs is recorded.30 Acute septicemic disease in grower pigs aged 14–22 weeks and associated with serotype D has been recorded in Australia.18 Recently,32 an outbreak of hemorrhagic septicemia was recorded in Australia. In the past, hemorrhagic septicemia was recorded in India in association with F. tularensis. Diverse outbreaks of hemorrhagic septicemia have also been recorded in Australia.30

**ETIOLOGY**

Francisella tularensis is the causative organism. It is Gram-negative, does not form spores and gives partial cross-agglutination with Brucella spp. Isolates are antigenically similar but they can be divided into two types on biochemical and epidemiological features and virulence tests. Type A, Francisella tularensis biovar tularensis, is prevalent in North America. Type B, Francisella tularensis biovar holarctica (palaearctica), is found in Asia, Europe and North America. Type A is associated with tick-borne tularemia in rabbits and type B is associated with mosquitoes and with water-borne disease in aquatic rodents. Type A is the more pathogenic of the two types and the more virulent for humans.1,3 Type B rarely causes disease in higher mammals.

**EPIDEMIOLOGY**

Tularemia is primarily restricted in its occurrence to countries in the northern hemisphere and occurs in most of them. In North America the disease is most prevalent in farm animals in the north-western states of the USA and the adjoining areas of Canada, although in these areas it is rare and the majority of reports in livestock are historical.

**Risk factors**

Animal risk factors

F. tularensis has a wide host range and is recorded in over 100 species of bird and wild and domestic animal. Disease is recorded among farm animals, most commonly in sheep and pigs and to a lesser extent in cattle and horses. F. tularensis is spread by ticks and mosquitoes. Tularemia is transmitted by ticks and mosquitoes. Tularemia is transmitted by ticks and mosquitoes. Tularemia is transmitted by ticks and mosquitoes. Tularemia is transmitted by ticks and mosquitoes.
Transmission

The major reservoirs and transmitters of the infection are rabbits, hares, wild rodents, ticks, and flies and the principal mammalian target host in North America is the cottontail rabbit (*Sylvilagus* spp.). With sheep, transmission occurs chiefly by the bites of the wood tick, *Dermacentor andersoni*, and from *Haemaphysalis leporispalustris*, the ticks becoming infected in the early part of their life cycle when they feed on rodents. In Europe *Ixodes ricinus* and *Dermacentor reticulatus* are vectors.

Trans-stadial and transovarial transmission occurs in the tick. The adult ticks infest sheep, and pastures bearing low shrubs and brush are particularly favorable to infestation. The ticks are found in greatest numbers on the sheep around the base of the ears, the top of the neck, the throat, axillae, and udder. It is assumed that sheep are relatively resistant to tularemia but become clinically affected when the infection is massive and continuous. Transmission to pigs and horses is thought to occur chiefly by tick bites but mechanical transmission to laboratory animals does occur with tabanids and blackflies.

Pathogen risk factors

There is little information concerning virulence mechanisms of *F. tularensis*. The capsule appears to be a necessary component for expression of full virulence and protects against serum-mediated lysis. The lipopolysaccharide has unusual biological and structural properties and low toxicity in vitro and in vivo. The organism can persist in dry straw for 6 months, persists for at least 16 months in mud and water and may proliferate in these media. It does not appear to survive in carcasses for long periods unless they are frozen, when it may persist for 60–120 days.

Zoonotic implications

*F. tularensis* biovar *tularensis* has remarkable invasive powers and infection in humans can occur through the unbroken skin. Most exposures appear to result from handling of infected rabbits and other wildlife but infections can arise from bites of ticks and the deer fly (*Chrysops discalis*), from the ingestion of contaminated meat and water, and from the bite or scratch of infected cats. The disease is an occupational hazard to workers in the sheep industry in areas where the disease occurs. Spread of the disease to humans may also occur in abattoir workers who handle infected sheep carcasses. Shearers are susceptible because outbreaks often occur at shearing time. The inhalation or intradermal injection of as few as 10 organisms can establish infection in humans, and appropriate precautions should be taken in the clinical and postmortem examination of suspect cases. The organism is identified as a potential agent of bioterrorism.

Pathogenesis

Tularemia is an acute septicemia but localization occurs, mainly in the parenchymatous organs, with the production of granulomatous lesions.

Clinical findings

Sheep

The incubation period has not been determined. A heavy tick infestation is usually evident.

The onset of the disease is slow with a gradually increasing stiffness of gait, dorsiflexion of the head and a hunching of the hindquarters; affected animals lag behind the group. The pulse and respiratory rates are increased, the temperature is elevated up to 42°C (107°F), and a cough may develop. There is diarrhea, the feces being dark and fetid, and urination occurs frequently with the passage of small amounts of urine. Body weight is lost rapidly, and progressive weakness and recumbency develop after several days, but there is no evidence of paralysis, the animal continuing to struggle while down. Death occurs usually within a few days but a fatal course may be as long as 2 weeks. Animals that recover commonly shed part or all of the fleece but are solidly immune for long periods.

Pigs

The disease is latent in adult pigs but young piglets show fever up to 42°C (107°F), accompanied by depression, profuse sweating, and dyspnea. The course of the disease is about 7–10 days.

Horses

In horses, fever (up to 42°C, 107°F) and stiffness and edema of the limbs occur. Foals are more seriously affected and may show dyspnea and incoordination in addition to the above signs.

Clinical pathology

An agglutination test is available for the diagnosis of tularemia, a titer of 1:50 being regarded as a positive test in pigs. Serum from pigs affected with brucellosis does not agglutinate tularemia antigen, but serum from pigs affected with tularemia agglutinates brucellosis antigen. Cross-agglutination between *F. tularensis* and *Brucella abortus* is less common in sheep and an accurate diagnosis can be made on serological grounds because of the much greater agglutination that occurs with the homologous organism. Titers of agglutinins in affected sheep range from 1:640 to 1:5000 and may persist at levels of 1:320 for up to 7 months. A titer of 1:200 is classed as positive in sheep. In horses the titers revert to normal levels in 14–21 days.

An intradermal sensitivity test using 'tularin' has been suggested as being more reliable as a diagnostic aid in pigs than the agglutination test, but is unreliable in sheep.

Necropsy findings

In sheep, large numbers of ticks may be present on the hides of fresh carcasses. In animals that have been dead for some time, dark red subcutaneous areas of congestion up to 3 cm in diameter are found and may be accompanied by local swelling or necrosis of tissues. These lesions mark the attachment sites of ticks. Enlargement and congestion of the lymph nodes draining the sites of heaviest tick infestation are often noted. Pulmonary edema, congestion, or consolidation are inconstant findings.

In pigs the characteristic lesions are pleuritis, pneumonia, and abscission of submucosal and parotid lymph nodes. The organisms can be isolated from the lymph nodes and spleen, and from infected ticks. Isolation can also be effected by experimental transmission to guinea pigs. Techniques such as immunoperoxidase staining of fixed specimens and PCR of fresh tissues can circumvent the need for culture of this zoonotic agent.

Samples for confirmation of diagnosis

- Bacteriology - lung, lymph node, spleen (CULT - requires cystine-enriched media, PCR)
- Histology - above tissues plus liver, fixed in formalin (LM, IHC)

Note the zoonotic potential of this organism when handling carcasses and submitting specimens.

Differential diagnosis

The occurrence of a highly fatal septicemia in sheep during spring months when the sheep are heavily infested with *Dermacentor andersoni* should suggest the possibility of tularemia, especially if the outbreak occurs in an enzootic area.

- Tick paralysis. This occurs in the same area and at the same time of the year as tularemia but is not accompanied by fever and there is marked flaccid paralysis. Recovery from tick paralysis occurs commonly if the ticks are removed.
- Other septicemias include *P. trehalosi* in sheep and *Haemophilus* sp. in sheep and cattle. These are unusual in the age group in which tularemia occurs and are not associated with tick infestation. In pigs, local lesions can resemble tuberculosis.
- Anthrax.
TREATMENT
Streptomycin, gentamicin, the tetracyclines, and chloramphenicol are effective treatments in humans and companion animals. Oxytetracycline (6–10 mg/kg BW) has been highly effective in the treatment of lambs and much more effective than penicillin and streptomycin. 

CONTROL
An outbreak of tularemia in sheep can be rapidly halted by spraying or dipping with an insecticide to kill the vector ticks. In areas where ticks are enzootic, sheep should be kept away from shrubby, infested pasture or sprayed regularly during the months when the tick population is greatest. An experimental live attenuated vaccine has been developed but there is no routine vaccination of livestock.

REVIEW LITERATURE

REFERENCES

YERSINIOSIS

Etiology
Yersinia pseudotuberculosis and Yersinia enterocolitica cause occasional disease in farm animals under special circumstances. These organisms also are increasingly recognized as a cause of disease in humans and this is their main importance.

Epidemiology
Subclinical and clinical disease in ruminants associated with either organism in animals that are debilitated from other influences. Enterococci is an emerging form of infection. Pigs carry Y. enterocolitica in the tonsils, pharynx, and intestine but the epidemiology of infection is poorly established.

Clinical findings
Ruminants: chronic ill-thrift and in a wasted condition with or without diarrhea.

Diagnostic confirmation
Culture. PCR

ETIOLOGY
There are pathogenic and nonpathogenic strains of Yersinia pseudotuberculosis and Yersinia enterocolitica. The pathogenic strains of both organisms possess chromosomal and plasmid-mediated virulence determinants.

Y. pseudotuberculosis can be divided into 15 major serogroups, based on O-antigens, some of which can be further divided into subgroups on the basis of type-specific somatic and flagellar antigens. There is variation in animal and human pathogenicity between the serogroups.

Y. enterocolitica is divided into five biotypes. It is serologically heterogeneous and 27 serotypes have been identified on the basis of somatic and flagellar antigens with further subdivisions. Bioserotypes may be host-specific. Serotypes O2, O3, O5, O8, and O-9 have been associated with infection in farm animals and humans, whereas other serotypes appear to be nonpathogenic. Serotype O-9 is antigenically very similar to Brucella spp., and infection with this serotype is a cause of false-positive reactions to Brucella agglutination and complement fixation tests.

EPIDEMIOLOGY
Occurrence
Yersinia has worldwide occurrence, although there appear to be regional differences in the species of animal infected, the prevalence of disease and the organism involved. Y. pseudotuberculosis has historically been associated with sporadic pyemic disease in sheep manifest with extensive abscessation of internal organs such as liver and spleen. More recently it, and Y. enterocolitica, have been associated with enterocolitis occurring in cattle, sheep, pigs and goats, and feral deer. Enteric disease in ruminants has been particularly reported in recent years from Australia and New Zealand.

Yersinia pseudotuberculosis
Y. pseudotuberculosis is a common inhabitant of the intestine in a wide variety of domestic and wild mammals. Wild birds and rodents are also reservoirs of the organism, and fecal–oral spread on pastures and in water is a major method of transmission. Spring migratory birds can spread pathogenic types over long distances.

There may be differences in the host specificity of different serotypes and strains. Rodents and birds may be the major reservoirs for serotypes I and II, which infect deer and goats, whereas sheep and cattle may be a maintenance host for serotype III.

In an Australian study Y. pseudotuberculosis serotype III was isolated from the feces of healthy sheep in 5% of flocks examined and the prevalence was probably much higher as both a small number of sheep were sampled in each flock. Infection was more common in young sheep, occurred during the winter and spring months, and remission of the organism persisted for 1–14 weeks.

In cattle the organism has been found without disease in 26% of normal cattle and on 84% of farms tested. The fecal excretion that occurs in clinically normal sheep and cattle possibly results from a subclinical infection of the intestine, as experimental challenge of ruminants can result in the establishment of the organism in the intestine with the presence of microscopic abscessation in the mesentery and serosal conversion in the absence of clinical disease.

Enteric disease associated with this organism in both cattle and sheep appears to occur as the result of a heavy infection pressure in animals that are debilitated from other influences. These include cold wet weather, inanition and starvation, trace element deficiency, change of diet, management procedures such as marking and, in farmed deer, procedures such as capture, yarding, and recent transport.

In sheep, attack rates in the flock for clinical disease have ranged from 1%–90% with a mean of 18% and a population mortality varying from 0–6.7%.

Y. pseudotuberculosis may also cause sporadic abortion in cattle, sheep, and in pregnant sheep, abortion occurs during the latter part of pregnancy and without clinical illness in the ewe. The organism is the cause of occasional cases of bovine caprine mastitis, and epididymitis, and orchitis in rams, and it may be found in sporadic cases of abscessation and lymphangitis in ruminants.

Yersinia enterocolitica
Y. enterocolitica is not commonly associated with clinical disease in farm animals. Diarrhea associated with this organism can occur in sheep, and the organism can be isolated from affected lambs. However pathogenic strains of Y. enterocolitica are less pathogenic to sheep and goats than pathogenic strains of Y. pseudotuberculosis.

Enterocolitis is recorded in sheep and goats. Biotype 5, serotype O-2,3 has been isolated from some of these. In an Australian survey this organism was detected in 17% of flocks and was isolated from young sheep at all seasons of the year. Clinical disease appears to be predisposed by the same stress factors as apply with disease associated with Y. pseudotuberculosis. Disease is recorded in sheep under 1 year of age.
of age with an attack rate that varied from 2-55% and a population mortality that ranged from 0.3-16.7%. Y. enterocolitica is also an occasional cause of abortion in sheep and this has been reproduced experimentally.19

Whereas Y. enterocolitica is commonly isolated from pigs, and pigs are a major reservoir for human disease, it is a rare cause of clinical disease in conventional pigs, although clinical enteric disease can be produced by experimental challenge of colostrum-deprived pigs.20 Conventional pigs challenged with serotype 03 excreted the organism in feces but were fecal-culture-negative 10 weeks after challenge and at slaughter, even though the organism could be isolated from the tonsils at slaughter. Pigs seroconverted at day 19 postchallenge and remained sero-positive until slaughter 70 days later.20

Zoonotic implications

*Yersinia pseudotuberculosis*

Human infection with *Y. pseudotuberculosis* is primarily manifest with septicaemia, and renal failure is a sequel. In addition to food-borne infection the consumption of water contaminated by animal feces appears to be a major risk factor. Raw milk consumption is also a risk.22

*Yersinia enterocolitica*

Gastrointestinal disease associated with *Y. enterocolitica* appears to have increasing prevalence in humans and can be associated with a reactive arthritis as a sequel. Septicemia does occur but is largely limited to those with other underlying disease. Serotypes O:3, O:5, O:8, and O:9 are incriminated. Pigs are a major reservoir for *Y. enterocolitica*, and pork and pork products are sources for human infection. Serotype O:3, in particular, is commonly isolated from the tonsils and pharynx of pigs at slaughter and less commonly from feces. The rate of isolation varies geographically and with farm source and it has been suggested that pathogen-free breeding is a method for control.23

In contrast to Australia and New Zealand, it is believed that in Europe the pig is the only domestic animal consumed by humans that regularly harbors pathogenic *Yersinia*.24 There is an apparent increasing prevalence of O:3 infections in humans in the northern hemisphere and pigs and pork products are considered to be important sources.24,25 A survey in Great Britain comparing isolates of *Y. enterocolitica* from cattle, sheep, and pigs with those from humans over a 2-year period did not find a strong correlation between pathogenic serotypes isolated from the two groups, with the exception of isolates from pigs.26 The importation of meat products has been incriminated as the vehicle of introduction of pathogenic serotypes into Japan.27 There would appear to be an increased risk for infection in humans handling pigs at slaughter and in veterinarians in pig practice.

**PATHOGENESIS**

Invasion of the intestinal epithelium is followed by inflammation in the mucosa and the formation of microabscesses in the lamina propria and mesenteric lymph nodes. Ulcers and disruption of the intestinal mucosa lead to loss of fluid and function. The intestinal lesions are accompanied by villous atrophy and lead to malabsorption and ill-thrift, diarrhea or a combination of the two.13

**CLINICAL FINDINGS**

Affected animals may present with a syndrome of chronic ill-thrift and in a wasted condition with or without diarrhea. Where diarrhea is present the feces are watery, foul-smelling, and black in color, but occasionally they also contain mucus and blood. Diarrhea persists for 2-6 weeks in an individual animal and may require yarding and dagging as control procedures to avoid fly strike.

**CLINICAL PATHOLOGY**

There is a neutrophilia with a left shift. Affected animals are often hypoproteinemice and anemic, although this may be a reflection of the underlying malnutrition. In experimental infections antibody develops by 9-19 days postinfection and may be an aid to diagnosis.5,30 The organism can be isolated from the feces. A multiplex PCR is capable of detecting 10 pathogenic serobiotypes of *Y. enterocolitica*28 and PCR has been developed to discriminate pathogenic *Y. enterocolitica* from other members of this genus.29

**NECROPSY FINDINGS**

There are liquid intestinal contents but usually no gross findings. Some sheep may have thickening of the mucosa of the small intestine and the cecum and colon, and the mesenteric lymph nodes may be enlarged and edematous. The characteristic findings on histopathology consist of a segmental suppurative erosive enterocolitis.15 Microabscesses, consisting of aggregations of neutrophils with prominent colonies of Gram-negative coccobacilli, are present in the mucosa. Lesions are most prevalent in the jejunum and ileum and are accompanied by atrophy of villi, and hyperplasia of crypt epithelium. Microabscesses may coalesce to produce erosive erosions and there may be microabscesses in the liver. The placenta from sheep that have aborted in association with *Y. pseudotuberculosis* is thickened and edematous with necrotic debris in the intercotyledonal zone and must be differentiated from enzootic abortion.14

**Sampless for confirmation of diagnosis**

- Bacteriology - jejunum, ileum, colon, mesenteric lymph node (CULT sometimes requires cold enrichment)
- Histology - formalin-fixed jejunum, ileum (several sections), colon, mesenteric node (LM).

Note the zoonotic potential of this organism when handling carcasses and submitting specimens.

**DIFFERENTIAL DIAGNOSIS**

The major differential is the syndrome of weaner ill-thrift.

**TREATMENT AND CONTROL**

Isolates vary in their sensitivity to antibiotics and a sensitivity test is advisable. Most isolates show in vitro sensitivity to the aminoglycosides, to tetracyclines and to sulfonamides or a combination of sulfonamides and trimethoprim.13,23,30 Sulfonamides and trimethoprim are reported not to be effective in the treatment of yersiniosis in cattle; long-acting tetracyclines are recommended for the treatment of both infections, in combination with supportive therapy.31

There is no specific control but the maintenance of good nutrition is believed to be an important factor in avoiding clinical disease.

PROGRESSIVE ATROPHIC RHINITIS (TURBATIVE ATROPHY OF SWINE)

Atrophic rhinitis is a disease affecting primarily young pigs but causing anatomical lesions which may persist for life. The term nonprogressive atrophic rhinitis is used for the slight to severe rhinitis and usually transient turbinate atrophy in which no toxigenic *P. multocida* are found, when there are no clinical signs and no obvious growth retardation. This mild form is probably as a result of infection with *Bordetella bronchiseptica* and/or nontoxigenic *P. multocida*. The term progressive atrophic rhinitis is proposed for the infection with toxigenic *P. multocida* (capsular serotype D and A strains) characterized by shortening or distortion of the snout, sneezing, nasal discharge, and epistaxis. Progressive atrophic rhinitis is often accompanied by reduced growth rates in severe cases.

**Synopsis**

**Etiology** Toxigenic strains of *Bordetella bronchiseptica* and *Past. multocida*

**Epidemiology** Young growing pigs. High percentage of pigs reared under intensive conditions may have some degree of atrophic rhinitis. Infection widespread and transmitted by carrier sow to piglet. Housing and ventilation risk factors. Immunity develops in herd. Major economic importance because may affect growth rate and predispose to pneumonia

**Signs** Initially sneezing when piglets 3–9 weeks of age. Nasal discharge. Deformity of face with nasal bones (twisted snout). Growth rate may be decreased

**Clinical pathology** Culture organism from nasal swabs. PCR

**Lesions** Varying degrees of severity of atrophic rhinitis

**Diagnostic confirmation** Necropsy examinations of snouts

**Differential diagnosis list**
- Inclusion body rhinitis
- Necrotic rhinitis
- Inherited prognathia

**Treatment** Antimicrobials in early stages; nothing later

**ETIOLOGY**

Infection of the nasal cavities with *B. bronchiseptica* followed by toxigenic strains of *P. multocida* – primarily capsular type D and occasionally type A – results in progressive turbinate atrophy. *P. multocida* type A strains were formerly thought to be associated entirely with lung infections but there is increasing evidence that some strains of *P. multocida* type A are increasingly toxin producers and may be involved in atrophic rhinitis. Toxin production appears to be independent of serotype. The strains of *P. multocida* isolated from the lungs are usually nontoxigenic and of capsular type A but a small proportion are toxigenic and/or possess capsular type D. A complex study of the porcine strains with progressive atrophic rhinitis and pneumonia has been completed. Eighteen groups of strains were identified on the basis of specific combinations of capsular type, taxA status and outer membrane protein (OMP) type. The majority (88%) of cases of pneumonia were associated exclusively with nontoxigenic capsular type A strains of OMP types 1.1, 2.1, 3.1, and 5.1 and capsular type D isolates of OMP6.1. They are primary pathogens with a relatively high degree of virulence. In contrast the majority (76%) of cases of progressive atrophic rhinitis were associated with toxA-containing capsular type D strains of OMP4.1 and capsular type A and D strains of OMP6.1. They further found that toxigenic capsular type A strains associated with progressive atrophic rhinitis and nontoxigenic strains of capsular type A associated with pneumonia represented separate populations of *P. multocida* recognizable by their OMP types.

**EPIDEMIOLOGY**

**Occurrence** Atrophic rhinitis occurs worldwide where pigs are reared under intensive conditions. It has, however, become much less important with the onset of vaccination, improvement in resistance by pig breeding companies and general attention to the environment in the farrowing house. It is one of the most common diseases in pigs in the midwestern USA. Some surveys have shown that 50% of finished pigs and sows at slaughter have lesions of atrophic rhinitis. The incidence of clinical disease varies from 5–30%, which in part depends on the method of detection of the gross lesions. Abattoir surveys of the snouts of slaughtered pigs indicate that the incidence of gross lesions ranges from 14–50%. However, the incidence of gross lesions in abattoir surveys is biased by the source of the pigs; the incidence may be low in pigs from herds that have attempted to control the disease and high in some commercial herds with no control program. In pigs slaughtered from pig testing stations the incidence of lesions may be uniform over a long period. The published data on the incidence of gross lesions are also variable because of the lack of a uniform method of evaluating and quantifying the lesions. However, major improvements in the development of uniform and repeatable methods of evaluating lesions have occurred in recent years.

The incidence and severity of the lesions may vary with the season and the type of facility in which pigs are reared. In a slaughter survey of the snouts and lungs of pigs from 21 pig herds over one winter and one summer the lesions of atrophic rhinitis were more severe among pigs slaughtered in the summer, whereas lesions of pneumonia were more severe among pigs slaughtered in the winter. Lesions of atrophic rhinitis were also more severe in pigs farrowed in central, enclosed farrowing houses and finished in enclosed, mechanically ventilated buildings than in pigs farrowed individually in sow huts and finished on dirt lots. It is possible that the incidence and severity of the lesions at slaughter may be a reflection of the condition of the housing facilities when the animals were piglets several months previously, but many other factors could have been involved.

**Prevalence of infection**

*B. bronchiseptica* readily colonizes the ciliated mucosa of the respiratory tract of pigs and infection of the nasal cavities of pigs is present in almost every pig herd, with the prevalence of infection in pigs in commercial herds varying from 25–50%. Serological surveys of individual herds have found that up to 90% of the pigs are positive, which indicates that there is no reliable correlation between the frequency of isolation of the organism and the percentage of animals with antibody. The prevalence of infection is just as high in specific-pathogen-free herds as in non-specific-pathogen-free herds.

The prevalence of infection of toxigenic *P. multocida* type D is higher in herds with clinical disease. The organism can be present in 50–80% of weaned pigs in a herd with clinical disease in the finishing pigs. Toxigenic type D *P. multocida* was first detected in New South Wales, Australia, in 1986; in all herds examined, the introduction of pigs from an infected herd in South Australia was associated...
with an increased risk of infection.\textsuperscript{12} Toxigenic \textit{P. multocida} type D has been isolated rarely from herds free of atrophic rhinitis.\textsuperscript{13}

Whereas \textit{B. bronchiseptica} is eliminated from the respiratory tract of most infected pigs, leaving only a few infected at slaughter, \textit{P. multocida} often persists.

**Method of transmission**

Direct contact and droplet infection are presumed to be the most likely methods of transmission. The reservoir of infection is the infected sow, and litters of piglets become infected at an early age. Colonization of the tonsil by \textit{P. multocida} in conventionally reared pigs is common.\textsuperscript{14} In the Netherlands it has been recognized that infection is usually by one of four possibilities.\textsuperscript{15} These are artificial insemination centers, laborers, neighborhood infection by direct aerosol or indirect local contact, and the presence of carrier animals and birds.

The infection is usually introduced into a herd by the purchase of infected pigs. Spread between piglets is probably enhanced after weaning when mixing of litters occurs and 70–80\% of a large weaned group become infected. Infection persists for up to several weeks and months, followed by a gradual reduction in the intensity and rate of infection. In herds where \textit{B. bronchiseptica} is the initiating agent, up to 90\% of pigs 4–10 weeks of age will have nasal infection, but this infection rate falls to approximately 15\% by 12 months of age and the proportion of carrier pigs within the breeding herd decreases with increasing age of sow. The prevalence of infection is also much higher during the period from October to March than at other times of the year, and the prevalence of serologically positive animals is highest from July to December. This is most probably a result of the winter housing conditions, with few air changes per hour, fluctuating temperatures, and high humidity.

The epidemiology of toxigenic strains of \textit{P. multocida} as a causative agent of atrophic rhinitis is not as well understood. The organism colonizes the tonsils of clinically normal pigs. In contrast to \textit{B. bronchiseptica}, which is ubiquitous in pig herds the toxigenic isolates of \textit{P. multocida} appear to be restricted to herds affected with progressive atrophic rhinitis.\textsuperscript{9} The organism is invariably present in herds with progressive atrophic rhinitis but may also be present in about 5\% of the pigs in a herd with no clinical history of atrophic rhinitis. The main source of toxigenic isolates of \textit{P. multocida} for young pigs appears to be the pharyngeal tissues of the breeding stock. About 10–15\% of sows in farrowing houses may be infected with toxigenic isolates and piglets become infected within a week after birth. In contrast to \textit{B. bronchiseptica}, infection of piglets at 12–16 weeks of age with toxigenic \textit{P. multocida} will still result in varying degrees of severity of lesions. It is possible for growing pigs to develop lesions of atrophic rhinitis well beyond the age of 3 weeks if they are exposed to pigs affected with disease and infected with \textit{P. multocida} and \textit{B. bronchiseptica}.

**Risk factors**

**Animal risk factors**

The age at which piglets first become infected with \textit{B. bronchiseptica} has an important effect on the development of lesions. The most severe lesions occur in nonimmune animals infected during the first week of life. Animals infected at 4 weeks of age develop less severe lesions, while those infected at 10 weeks do not develop significant lesions.

**Immune mechanisms**

The level of immunity in the young pigs will influence the level of infection and the incidence of clinical disease. Colostal immunity from sows serologically positive to \textit{B. bronchiseptica} is transferred to piglets and provides protection for 2–5 weeks. Clinical disease does not occur in piglets with high levels of passive antibody. Older pigs from 10–12 weeks of age may become infected but are less likely to develop severe turbinate atrophy and may develop inapparent infection and become carriers.

Vaccination of the sow before parturition to increase colostral immunity or vaccination of the young piglet to increase colostral immunity or vaccination of the young pig will increase the position had changed to the opposite. All dromercnecot-toxin-positive pigs had pneumonia but the dromercnecot-toxin-positive animals were able to colonize the lung more freely. There is an outer membrane protein P68 peractin (\textit{B. bronchiseptica} peractin gene \textit{prn}) that is an adhesin, which may play a part in the protective immunity\textsuperscript{24} and may be extremely variable.\textsuperscript{25} The most important experiment is that one that shows that \textit{P. multocida} mutant strains without the capacity to produce \textit{P. multocida} type D toxin did not produce turbinate atrophy.\textsuperscript{26} Only certain porcine phase 1 cultures possess both properties. However, even the most virulent of 10 isolates of \textit{B. bronchiseptica} did not cause progressive turbinate atrophy or significant snout deformation in experimental infections. The severe lesions of atrophic rhinitis cannot be attributed to this organism alone. Experimental inoculation of specific-pathogen-free or gnotobiotic pigs with the organism resulted in a nonprogressive moderately severe turbinate atrophy 2–4 weeks after infection, followed frequently by regeneration of the turbinates. These virulence characteristics of \textit{B. bronchiseptica} are consistent with the observations that in herds where the organism is common it can provoke sneezing and coughing but no evidence of clinical turbinate atrophy. Examination of the turbinates within 2 weeks after the sneezing will reveal some mild lesions but no lesions will be evident when the pigs are examined at slaughter. It may be that the adhesins left over in the nasal cavity from an infection of \textit{B. bronchiseptica} are subsequently available for the attachment of other bacteria.\textsuperscript{27} Toxigenic isolates of \textit{P. multocida} colonize the nasal cavities, elaborate several toxins, and produce progressive lesions of the turbinate bones and snout. Toxigenic \textit{P. multocida} can colonize the upper respiratory tract of pigs\textsuperscript{28} and the presence of the capsule is a virulence factor. The presence of \textit{B. bronchiseptica} can enhance the colonization of...
P. multocida, particularly the toxigenic type D strains isolated from pigs. The cytotoxin of B. bronchiseptica is required for optimum growth by toxigenic P. multocida; other products of phase 1 B. bronchiseptica growth assist colonization by P. multocida, and the degree of atrophy of the turbinates in these mixed infections is related to the numbers of toxigenic P. multocida in the nasal cavity. 

Severe turbinate damage and shortening of the snout can be reproduced in specific-pathogen-free and gnotobiotic pigs by combined infection with B. bronchiseptica and certain strains of P. multocida. Following experimental infection both organisms may persist in the nasal cavities for up to 64 days. The cell envelope proteins and lipopolysaccharides of P. multocida strains associated with atrophic rhinitis have been characterized and compared. At least three protein patterns and six lipopolysaccharide patterns can be distinguished, which can be used to predict the pathogenic character of some of the strains. This will obviate the need to use the guinea-pig skin test to distinguish those strains that are associated with atrophic rhinitis and those that are not.

The gene for the osteolytic toxin of P. multocida has been cloned and expressed in E. coli; the protein expressed has been shown to have the same properties as the native toxin. The toxin is the major colonization factor produced by toxigenic strains of the organism and antitoxin made from the toxin is protective experimentally and cross-protective between toxins from different capsule types. 

The toxin can produce turbinat atrophy when injected intranasally and also when given intramuscularly, intra-peritoneally, intravenously, or intradermally. Fingerprinting techniques have been used to show that outbreaks of atrophic rhinitis since 1985 in Australia have been associated primarily with a single strain of toxigenic type D P. multocida.

Environmental factors
The effects of housing, population density and adequacy of ventilation on the prevalence of infection of B. bronchiseptica and toxigenic isolates of P. multocida, and on the incidence and severity of atrophic rhinitis, have not been examined in detail. Atmospheric ammonia, dust, and microbial concentrations in the farrowing house and dust in weaner barns have a significant role in the severity of atrophic rhinitis. 

The mean daily gain of pigs with atrophic rhinitis exposed to ammonia may be smaller than that of those not affected. Undocumented field observations suggest that the disease is more common and severe when pigs are confined, overcrowded and housed in poorly ventilated unsanitary barns, all of which promote the spread of infection.

There is no effect of high levels of ammonia on the severity of turbinate atrophy. It has been shown that high levels of ammonia have no effect on the disease progression of atrophic rhinitis and pneumonia but do enhance the colonization of the nasal turbinates by toxigenic P. multocida. A recent experiment has shown that higher numbers of P. multocida bacteria were isolated from the tonsil than the nasal membranes per gram of tissue. Aerial pollutants contribute to the severity of lesions associated with atrophic rhinitis by facilitating colonization of the upper respiratory tract by P. multocida.

Management factors such as confinement, crowding and the use of continual throughput farrowing houses and weaner houses are also considered to be important risk factors. Adverse climatic conditions (below thermoneutrality with drafty periods) can result in a lower amount of energy available for production because of increased maintenance requirements, which results in growth retardation associated with lowered feed intake.

Economic importance
Historically, it was accepted as dogma that atrophic rhinitis was an important cause of economic loss in pig herds because of decreased growth rate, less than optimal feed efficiency and the fact that it was a major risk factor in enzootic swine pneumonia. A number of field studies have found an association between atrophic rhinitis and reduced growth rate in some herds, whereas other observations were unable to show an association between the presence of the disease and growth rate. The lack of a standard system for evaluation of conchal lesions may be a factor in the variable results between observations.

Some field studies have failed to show that the disease has an effect on growth rate in finishing pigs or that there is a cause and effect relationship between atrophic rhinitis and pneumonia. The presence of pneumonia in pigs from a test station reduced mean daily weight gains by 33% for each 10% of affected lung, but atrophic rhinitis did not affect daily gain and there was no association between the development of atrophic rhinitis and the development of pneumonia. Pigs vaccinated against B. bronchiseptica had turbinobone atrophy scores or mean daily gains no different from those of unvaccinated pigs. In another study there was no low positive correlation between the herd mean turbinate atrophy score and the herd mean percentage pneumonia score. A recent report from Illinois indicates that the prevalence of clinical atrophic rhinitis in farrow-to-finish herds ranged from 0–20% and in pigs from those herds examined at the abattoir the incidence of turbinate lesions ranged from 5–92%. In some of the herds the mean daily weight gain was 15–18% higher than in herds where pigs had severe turbinate lesions. In an Australian report there was no correlation between the severity of atrophic rhinitis and growth rate or back fat thickness.

In one study of three commercial pig herds, the snouts and lungs of individual pigs were examined and scored at slaughter and the results were correlated with growth indicators for each pig (average daily gain during the growing and finishing phases, and days to reach market). Scores for lung lesions were also correlated to scores for snout lesions. Contrary to findings in many other studies, pigs that reached market weight at the youngest age did not have the lowest score for lung lesions, nor the lowest grade for snout lesions, nor the least extensive or severe lesions. It was concluded that lung lesions and grades for snout lesions in pigs at slaughter are not valid indicators for determining the economic effect of either pneumonia or atrophic rhinitis on growth performance of pigs.

PATHOGENESIS
Following infection of the nasal cavity, B. bronchiseptica becomes closely associated with the ciliated epithelium of the respiratory tract. The organism produces a heat-labile toxin that results in a non-progressive, moderately severe turbinate atrophy that is apparent within 2–4 weeks after infection, followed frequently by regeneration of the conchae. There is, initially, ciliary loss and ciliary stasis, followed by reduction in mucociliary clearance followed by hyperplasia and metaplasia of the nasal epithelium, fibrosis in the lamina propria, and resorption and replacement fibrosis of the osseous core. Experimental infection with B. bronchiseptica alone does not result in severe persistent conchal atrophy or twisting or shortening of the snout. The strains of B. bronchiseptica that produce cytotoxin may predispose to the colonization of P. multocida in the nasal cavities.

Infection and colonization of the nasal cavities with the toxigenic strains of P. multocida results in the elaboration of a toxin that causes progressive conchal atrophy. The toxin is thermolabile and demroncrotic and is called the demroncrotic toxin of P. multocida. The inoculation of a toxin from a toxigenic strain of type D P. multocida into the nasal cavities of gnotobiotic pigs results in severe atrophic rhinitis or in piglets. This toxin acts to promote the spread of infection.
The nasal cavity, y associ­mation of the reduces a non-­turbinate 4-weeks by itself. There is, y stasis, mucociliatory asia and ianthem, ria, and sisis of the then result in ophy or e snout. 

Toxigenic strains of P. multocida have been isolated from nasal swabs, indicating the presence of toxigenic P. multocida in the porcine respiratory tract. The detection of P. multocida in nasal swabs is important for diagnosing atrophic rhinitis and for implementing appropriate management strategies to control the disease.

The clinical findings of atrophic rhinitis depend on the stage of the lesions. In acute cases in piglets 3–9 weeks of age, irritation of the nasal mucosa causes sneezing, some coughing, small amounts of serous or mucopurulent nasal discharge, and transient unilateral or bilateral epistaxis. The frequency of sneezing may be a measure of the incidence and severity of the disease. In piglets born from sows vaccinated with B. bronchiseptica and P. multocida vaccine before farrowing, followed by two vaccinations within 3 weeks of age, the frequency of sneezing at 3–9 weeks of age was much less than in piglets given only B. bronchiseptica vaccine. There may be rubbing of the nose against objects or on the ground. A watery ocular discharge usually accompanies this and may result in the appearance of dried streaks of dirt below the medial canthus of the eyes. There may be a decrease in growth rate. In infection with B. bronchiseptica these clinical signs will disappear spontaneously in a few weeks, when the pigs will appear normal. In severe cases, respiratory obstruction may increase to the point of dyspnea and cyanosis, and sucking pigs may have great difficulty in nursing. The nasal secretions become thicker and nasal bleeding may also occur.

In the more chronic stages, inspirated material may be expelled during paroxysms of sneezing. During this chronic stage, there is often pronounced deformity of the face due to arrested development of the bones, especially the conchae, and the accumulation of necrotic material in the nasal cavities. The nasal bones and premaxillae turn upwards and interfere with approximation of the incisor and, to a lesser extent, the molar teeth. There are varying degrees of brachygnathia superior and protrusion of the lower incisor teeth. Prenhension and mastication become difficult, with a resulting loss of body condition. Facial distortion in the final stages takes the form of severe 'dishing' of the face with wrinkling of the overlying skin.

If the condition is unilateral, the upper jaw may be twisted to one side. These visible facial deformities develop most commonly in pigs 8–10 weeks old within 3–4 weeks after infection, but they may occur in younger pigs.

The most serious effects of the advanced disease are depression of growth rate and unthriftiness. The appetite may be unaffected but much feed is lost by spillage and feed efficiency may be reduced in some instances.

**CLINICAL PATHOLOGY**

**Culture and detection of bacteria**

It is important to be able to detect infected animals in a herd, especially the carrier animal. Nasal swabs are used to detect the bacteria and to determine their drug sensitivity. The collection of the nasal swabs must be done carefully and requires a special transport medium to insure a high recovery rate. A sampling technique and a special culture medium to facilitate the isolation and recognition of B. bronchiseptica are described. The external nares are cleaned with alcohol and a cotton-tipped flexible wire is pushed into the nasal cavity (of each side in turn) until it reaches a point midway between the nostril and the level of the medial canthus of the eye. On removal, the cotton tip is cut off into 0.5 mL of an ice-cold sterile transport medium comprising phosphate-buffered saline (PBS, pH 7.3) with fetal calf serum (5% v/v). The samples are then placed on special media, preferably within 4 hours. Normally the organism grows well on conventional culture media, especially when younger pigs are sampled. However, in the carrier pig the organism may be sparse and the selective medium is recommended.

The nasal culturing procedure has been used as an aid in the control of atrophic rhinitis associated with B. bronchiseptica. A series of three nasal swabs from each animal is considered to be about 77% efficient in detecting infected animals for possible culling and elimination from the herd. However, in some studies there may be no marked difference in the prevalence of B. bronchiseptica or P. multocida in pig herds with or without clinical atrophic rhinitis.

Toxigenic P. multocida grow readily in the laboratory but are difficult to isolate from nasal swabs because they are frequently overgrown by commensal flora. Selective laboratory media containing antimicrobial agents have been developed to promote the isolation of P. multocida from nasal swabs. Inoculation of cotton swabs to selective medium on the same day as the sampling provides the best isolation of toxigenic P. multocida.
Immersion of pigs at slaughter in the scalding tank can result in a marked reduction in the isolation of toxigenic *Pasteurella multocida*.

A cell culture assay using embryonic bovine lung cells is available and is a sensitive *in vitro* test for the differentiation of toxigenic from nontoxigenic isolates of *Pasteurella multocida*. This test can replace the lethal tests in mice or the dermonecrotic tests in guinea-pigs.

**Serology**

Agglutination tests and an ELISA test are available for the detection of pigs infected with *B. bronchiseptica*, especially carrier animals. Serology is of value in the assessment of the response of pigs vaccinated with the *B. bronchiseptica* vaccines. There are currently no reliable serological tests for *Pasteurella*.

**Antigen detection**

A PCR method originally described in 1996 for the enhanced detection of toxigenic *Pasteurella multocida* directly from nasal swabs has been described and upgraded.51

This was shown to be 10 times more sensitive than *Pasteurella* type D toxin (PMT) ELISA and five times more sensitive than clinical bacteriology with subsequent use of PMT ELISA. A nested PCR has also been described.52 Similarly, a PCR method for the detection of *B. bronchiseptica* has been described that produces 78% more positives than culture, particularly with swabs with a high mixed bacterial load. Recently a nested-PCR has been described that was reported to be more specific and sensitive than the other PCR methods previously described.54 It does not require culture, it is less laborious and the results can be provided within 24 hours. The authors concluded that this was test was suitable for breeding company evaluations and for eradication schemes.

**Radiography**

Some aids to the clinical diagnosis have been examined but are not highly accurate. Radiography of the nose is not reliable in detecting the severity of conchal atrophy.

**NECROPSY FINDINGS**

The typical lesions of atrophic rhinitis are restricted to the nasal cavities, although concurrent diseases, especially virus pneumonia of pigs, may produce lesions elsewhere. In the early stages there is acute inflammation, sometimes with the accumulation of pus, but in the later stages, there is evidence only of atrophy of the mucosa, and atrophy and atrophy of the conchae and ethmoid bones, which may have completely disappeared in severe cases. The inflammatory and atrophic processes may extend to involve the facial sinuses. There is no evidence of interference with the vascular supply to the affected bones. The changes in the nasal cavities are most readily seen if the head is split in the sagittal plane but for accurate diagnosis the degree of conchal symmetry, volume and atrophy and medial septum deviation should be assessed by inspection of a vertical cross-section of the skull made at the level of the second premolar tooth.

The clinical diagnosis is confirmed and the severity of the lesions is assessed by the postmortem examination of a cross-section of the snout. The snout must be sectioned at the level of the second premolar tooth because the size of the conchal bone reduces anteriorly and may give a false-positive result if the section is taken too far forward. Quantification of the severity of the lesions has been of value for monitoring the incidence and severity of the disease in a herd. Several systems have been used for grading the severity of lesions of the snout. Most of them have used a subjective visual scoringsystem in which snouts are grade 0 (complete normality) to 5 (complete conchal atrophy). Reasonable agreement among observers recording morphological changes of nasal conchae is achievable with some training.53

The standards for each grade are as follows.55

**Grade 0**: No deviation from absolute normality, with nasal septum straight and conchae symmetrical and filling nasal cavities

**Grade 1**: Slight irregularity, asymmetry or distortion of the nasal structures without atrophy

**Grade 2**: Marked distortion of nasal structure but without marked atrophy

**Grade 3**: Definite atrophy of the conchae with or without distortion

**Grade 4**: More severe atrophy with severe atrophy of one or more conchae

**Grade 5**: Very severe atrophy in which all conchae have virtually disappeared.

Such a discontinuous grading system does not provide a direct quantitative relationship. Regular examination of the snouts from heads of pigs sent to slaughter can be used to assess the level of conchal atrophy in the herd. Morphometric methods, using either point counting or semi-automated planimetry applied to photographic or impression prints of sections of the snout to measure the extent of conchal atrophy on a continuous scale as a morphometric index, are now available. Cross-sections of the snout are photographed or used to make impression prints, which are then measured.56 A morphometric index is determined, which is the ratio of free space to total cross-sectional area of the nasal cavity. The system correlates well with the visual grading system of 0–5 but is labor-intensive and relatively expensive. The conchal perimeter ratio may be a more reliable morphometric measure of atrophic rhinitis and also provides parametric data suitable for quantitative analysis.57 A morphometric analysis using conchal area ratio is the best method for quantifying gross morphological turbinate changes.58 Descriptions of the methods for making snout impressions are available.59,60 Computed tomography has been described.61

A major limitation of the grading system is that conchal atrophy occurs as a continuous spectrum and it is difficult to decide, for example, if a pig with a grade 3 lesion represents the more severe manifestation of *B. bronchiseptica* infection, which may not progress further, or an early manifestation of infection with toxigenic *Pasteurella multocida*, which could develop into a severe herd problem.

**Samples for confirmation of diagnosis**

- Bacteriology – nasal swabs
- Histology – formalin-fixed cross-section of snout at level of second premolar
- Antigen detection – nasal swabs.

**DIFFERENTIAL DIAGNOSIS**

The occurrence of sneezing in the early stages and of facial deformity in the later stages are characteristic of this disease.

Inclusion body rhinitis due to a cytomegalovirus is a common infection in young piglets in which there is sneezing and conjunctivitis. However, by itself it does not progress to produce turbinate atrophy and facial distortion. Under good hygienic conditions the course of the disease is about 2 weeks and the economic effects are minimal. In the early acute stages, atrophic rhinitis may be mistaken for swine influenza which, however, usually occurs as an outbreak affecting older pigs and accompanied by a severe systemic reaction without subsequent involvement of facial bones.

Necrotic rhinitis is manifested by external lesions affecting the face, and virus pneumonia of pigs is characterized by coughing rather than sneezing.

The inherited prognathic jaw of some breeds of pigs has been mistaken for the chronic stage of atrophic rhinitis; protrusion of the lower jaw is quite common in adult intensively housed pigs and has been attributed to behavioral problems of pushing the snout against fixed equipment such as bars and nipple drinkers.

**TREATMENT**

Treatment early in the course of the disease will reduce the severity of its effects, but it
Control of atrophic rhinitis can be attempted in at least four ways:
- Total eradication
- Reduction of infection pressure
- Mass medication with antimicrobials to reduce the severity and adverse effects of infection
- Vaccination.

Regardless of the method employed, any effective control program must have a system for monitoring the incidence of clinical disease in the herd and the incidence and severity of conchal lesions of the pigs sent to slaughter. Accurate and reliable methods for monitoring clinical disease are not available but the incidence of acute rhinitis and facial deformities could be recorded regularly. At slaughter, snouts can be examined for lesions of conchal atrophy and for assessing a mean snout score for each group of pigs slaughtered.

**Eradication**

Total eradication can only be achieved with confidence by complete depopulation for a 4-week period and repopulation with primary or purchased specific-pathogen-free stock. This approach has the added advantage of also eliminating enzootic pneumonia, which may be a significant contributing factor to the economic importance of this disease. However, this method of control is extremely costly and the economic importance of the disease would need to be carefully evaluated in relation to this cost before this method was instituted. Other techniques of obtaining pigs free of atrophic rhinitis, such as the isolated farrowing of older and presumed non-carrier sows with subsequent clinical and postmortem examinations of a proportion of the litters, have had a significant failure rate in the field and are not recommended. Eradication by repopulation with cesarean-derived stock may be essential in breeding nucleus herds where a high generation turnover results in a low herd sow age and a low herd level of immunity. The breakdown rate of herds established by this method can be significant, presumably because the initiating organisms are not solely confined to pigs.

A pilot control scheme was initiated in Britain in which a herd had to meet the following conditions:

- It must be inspected by a veterinarian every 6 months over a period of 2 years, over which time there must be no clinical evidence of atrophic rhinitis
- The herd owner must certify that atrophic rhinitis has not been suspected over the same time period
- Cross-sections of snouts taken from at least 30% of market pigs must be examined regularly by a veterinarian, and over a 2-year probationary period the average 6-monthly snout score must not exceed 0.5
- There must be no vaccination or treatment for atrophic rhinitis
- New breeding stock can be introduced only from other qualified herds or herds derived by hysterectomy, artificial insemination, or embryo transfer techniques.

Over a 5-year period 45 herds qualified at some stage, and 34 were still qualified at the end of 5 years. As of 1988, some herds had exceeded the snout score limit of 0.5, with their average scores increasing to 2.24. In these herds, there was no clinical, epidemiological, or bacteriological evidence that they were at risk of developing severe atrophic rhinitis. It is suggested that the higher scores were associated with a group of recurrent husbandry factors, especially overstocking and unsatisfactory conditions in the weaner barns. These increased scores suggested the possibility that the upper limit for the snout scores in qualifying herds could be raised and allow bacteriological testing to be confined to more doubtful herds.

Eradication in the Netherlands was based on the fact that they thought that there were four main possibilities for the spread of toxigenic *P. multocida*; artificial insemination centers, laborers, neighborhood infection either by aerosol or by local spread, and carrier animals or birds. They assumed that most herds were closed or buying certified stock and that the major source of infection was therefore the boar. In this study they tested boars; in herds with less than 50 boars they tested all and in those with more than 50 they tested 50 as the minimum. They took nasal and tonsil samples, which were placed in cold transport medium and sent to the laboratory within 24 hours under cooled conditions for overnight culture followed by PCR.

**Reduction of infection**

Reduction of infection pressure can be attempted. Infection of piglets occurs primarily either from carrier sows or from other infected piglets in the immediate environment and severe atrophic rhinitis generally results from infection of piglets under 3 weeks of age. If these factors can be minimized the incidence and severity of the disease can be reduced. An all-in/all-out pig flow is one of the most effective methods of control of atrophic rhinitis. Changing to an all-in/all-out pig flow from continuous flow management can improve snout scores by 50%, lung...

Diseases associated with Brucella species

**INTRODUCTION**

The species of *Brucella* and their principal farm animal hosts are *Brucella abortus* (cattle), *Brucella melitensis* (goats), *Brucella suis* (pigs), and *Brucella ovis* (sheep). In general, the principal manifestations of brucellosis are reproductive failure, such as abortion or birth of unthrifty newborn in the female, and orchitis and epididymitis with frequent sterility in the male. Persistent (life-long) infection is a characteristic of this facultative intracellular organism, with shedding in reproductive and mammary secretions. Brucellosis is also an important zoonosis causing debilitating disease in humans. Because of the major economic impact on animal health and the risk of human disease, most countries have attempted to provide the resources to eradicate the disease from the domestic animal population.

Control programs have employed two principal methods: vaccination of young or mature animals and the slaughter of infected and exposed animals, usually on the basis of a reaction to a serological test. Brucellosis has been eradicated from cattle in several regions of the world and is nearly eradicated in others. However, it is still widespread and is an economically important agricultural disease in many countries. There are still many cases of human brucellosis reported each year in regions where the disease has not been eliminated in farm livestock.

In 2002, an entire issue of the journal *Veterinary Microbiology*, vol 90, pp 1–603, was devoted to brucellosis. Several review articles on various aspects of brucellosis from that special issue are listed below under Review literature.

The history of brucellosis is fascinating. In 1884, Captain David Bruce and several others working on Mediterranean fever from human spleens. Hospital patients were fed raw goat’s milk for many illnesses and this was an early example of a nosocomial infection. The ship SS *Joshua Nicholson*, when anchored in Malta in 1905, took on board 65 goats bound for Washington. The Bureau of Animal Industry of the USDA had decided to import Maltese goats to encourage goat raising and tuberculosis were recognized as major causes of economic loss. By 1922, several states had passed laws and regulations in an attempt to prevent introduction of the disease in cattle purchased from other states. In 1930, concerns were raised about the relationship between the disease in animals and humans. The American Veterinary Medical Association recommended a field trial of a vaccine, which was developed from a strain of *Brucella abortus* strain 19. This vaccine has been used several decades as the most common immunizing agent for control of bovine brucellosis.

In 1934, a cooperative State Federal Brucellosis Eradication program was launched on a nationwide scale in the USA. A uniform plan provided for blood tests, slaughter of seropositive cattle and federal indemnities. In 1941, strain 19 was introduced and used in most states. All vaccinated cattle had to be properly identified. In 1934/35, the reactor rate in cattle tested was 11.5%. In 1954, the US Congress appropriated funds for a comprehensive national effort to eradicate brucellosis. The brucellosis eradication program was designed as a cooperative effort between the federal government, the states, and livestock producers. In 1957, shortly after the inception of the program, there were almost 124,000 infected herds identified. As of December 2004, there were no brucellosis-affected cattle herds in the USA; truly a success story in veterinary medicine. When brucellosis can be identified, contained

60. Lund LJ, Beckert PV, Vet Rec 1983; 113:473.
and eliminated before spread occurs, eradication can be achieved.

The evolution of the *Brucella* spp. and its taxonomy have been described in detail.\(^2\) In 2002, the genomes for *B. melitensis* were published, and *B. suis* and *B. abortus* are in their final stages.\(^3\) The proteomes of selected *Brucella* spp. have been extensively analyzed, all of which will provide opportunities to understand the complete biology of different *Brucella* species.\(^6\) The major outer membrane proteins of *Brucella* spp. have also been determined.\(^7\) The lipopolysaccharide of *Brucella* is unique and considered as a virulence factor that helps bacterial survival by circumventing the immune response.\(^8\) The pathology of brucellosis reflects the outcome of a battle between the host genome and the *Brucella* genome.\(^9\)

In addition to brucellosis occurring in terrestrial wildlife, *Brucella* spp. have been isolated from some marine mammals of North America\(^10\) and there is serological evidence of *Brucella* infection from several species of marine mammal from both hemispheres.\(^11\) Serological evidence of *Brucella* spp. has been found in odontocetes (suborder of toothed whales, including sperm whales, porpoises, grampus, dolphins, beaked whales, bottle-nosed whales, and narwhals) from the south Pacific and the Mediterranean.\(^11\)

### Status of brucellosis in regions of the world and countries

The status of brucellosis in regions of the world and countries varies considerably. The following is a summary of the status of brucellosis in various regions of the world as of 2002.

#### Romania

Romania, like many other developed countries, eradicated *B. abortus* from cattle in 1969.\(^12\) The incidence of brucellosis in sheep and pigs is rare and *B. melitensis* has never been reported. Vaccination against brucellosis is prohibited.

#### Countries in central and south-east Europe

In Macedonia and Greece, brucellosis occurs in sheep, goats, and humans, associated with *B. melitensis*.\(^13\) In Greece, cows are infected with *B. abortus* or *B. melitensis*. In Croatia, *B. suis* biovar 2 is found in pigs. In Yugoslavia, brucellosis is endemic in some regions. A financially well-supported control and eradication program such as that sponsored by the European Union is needed.

#### Kosovo

The overall serological prevalence of infection is 6.26% in sheep, 7.24% in goats and 0.58% in cattle.\(^14\) *B. melitensis* predominates as the cause of brucellosis in ruminants in Kosovo.

### Sub-Saharan Africa

Brucellosis is an important disease among livestock and humans in sub-Saharan Africa.\(^15\) The disease in cattle is prevalent and widespread and is caused primarily by *B. abortus*, *B. melitensis* and *B. suis* have been suspected. In sheep and goats, *B. melitensis* is common and the prevalence of infection is high. Brucellosis has occurred in pigs in these countries but information is limited. Brucellosis due to *B. abortus* is one of the most important diseases of camels in the arid and semi-arid pastoralist areas of central, east, and west Africa.

#### Eritrea

Seroepidemiological surveys for brucellosis in Eritrea found a prevalence of 8.2% in dairy cattle, with a herd prevalence of 35.9%.\(^16,17\) The prevalence in sheep and goats was variable depending on the geographical area. In camels, the seroprevalence was 3.1%.

#### Near East

In the near East region, animal brucellosis affects almost all domestic animals, particularly cattle, sheep, and goats.\(^18\) Brucellosis occurs in camels in Saudi Arabia, Kuwait, Oman, Iraq, Iran, Sudan, Egypt, Libya, and Somalia. In Egypt, brucellosis occurs in cattle, buffaloes, horses, and pigs. *B. melitensis* biovar 3 is the most commonly isolated species from animals in Egypt, Jordan, Israel, Tunisia, and Turkey. The highest incidence of human brucellosis occurs in Saudi Arabia, Iran, Palestinian Authority, Syria, Jordan, and Oman. Bahrain has none. Most human cases are associated with *B. melitensis*, biovar 3 but *B. abortus* is increasingly being reported in humans. The control of brucellosis in these countries is very controversial, with varying emphases on different aspects of control. The most commonly used vaccines are *B. abortus* strain 19, *B. melitensis* Rev. 1, and *B. abortus* RB 51.

#### Sri Lanka

*B. abortus* is a major cause of abortion among cattle and buffaloes.\(^19\) The incidence of the disease is low and the small size of the country would facilitate an effective disease control program.

#### India

Brucellosis was first recognized in India in 1942 and is endemic throughout the country.\(^20\) The disease occurs in cattle, buffalo, sheep, goats, pigs, dogs, and humans. *B. abortus* biovar 1 in cattle and buffaloes and *B. melitensis* biovar 1 in sheep, goats, and humans are the predominant infective biotypes. Economic losses are considerable in an agrarian country such as India. There is no organized and effective brucellosis control program. Plans for a large-scale control program, including calfhood vaccination, are underway.

A major constraint of a control program is that all slaughter of cows is banned and that segregation of seropositive cows until their death will therefore be necessary, but very costly.

#### China

Before the 1980s, human and animal brucellosis was severe. *B. melitensis* is most common in outbreaks.\(^21\) Sheep, cattle, and pigs are the main sources of infection for humans. Beginning in 1950, control programs have been in place and progress is being made towards control and eradication.

#### Brazil

Bovine brucellosis due to *B. abortus* is the most prevalent *Brucella* infection in Brazil, followed by *B. suis* in pigs. *B. melitensis* and *B. neotomae* have not been isolated. The prevalence of bovine brucellosis ranged from 4.5% to 8% in the period 1989–1998. The disease is considered endemic, with a higher incidence in regions with a higher cattle density.\(^22\) In 2001, a New National Program was launched, including compulsory vaccination of heifers aged 3–8 months, voluntary accreditation of free herds, voluntary monitoring of beef herds based on periodic sampling, regulatory tests for breeding stock prior to interstate movement and entrance into livestock fairs and exhibitions, compulsory slaughter of cattle testing positive, and standardization of testing procedures through short courses for accredited veterinarians.

#### Paraguay

Brucellosis has existed in the country for many years. Most reports are on *B. abortus* in cattle, but *B. melitensis* and *B. suis* have been identified. In 2000, it was estimated that the prevalence of *B. abortus* in the cattle population was 3.15%.\(^23\) A national campaign for the control and eradication of brucellosis was begun in 1978. The program is based on vaccination of calves at 3–8 months of age, testing and culling of seropositive animals, declaration of *Brucella*-free areas, and promotion of *Brucella*-free Herd Certification Programs in dairy herds. For beef herds there is mandatory vaccination, control of movement of animals intended for breeding, including testing for those imported, destined to fairs and auctions.

#### Venezuela

Brucellosis continues to be a serious disease for animal and human health in Venezuela.\(^24\) *B. abortus* is the most common biovar, causing high rates of abortion in cattle and buffalo. Based on the rapid agglutination plate test, the positive reactor rate ranges from 0.8–1.2%; using...
Brucellosis is endemic in the cattle, sheep, and goats of Argentina since the 19th century. In 2000, the individual cow prevalence was 10.5%. A control program mandates vaccination of all female dairy cattle, the prevalence is estimated at 7% between 3 and 8 months of age, and 2% by 24 months of age. The prevalence of infection in countries not officially brucellosis-free is extremely diverse. Countries not officially brucellosis-free are France, Greece, Ireland, Italy, Portugal, and Spain. The prevalence of infection in countries not free of brucellosis is extremely diverse. The highest numbers of infected herds occurred in southern Europe: Greece, Spain, Italy, and Portugal. The prevalence of infection has increased in both the Republic of Ireland and Northern Ireland. Both B. abortus and B. melitensis have been isolated from cattle; B. melitensis may cause isolated cases of abortion in cattle rather than outbreaks of abortion.

Great Britain has been free from brucellosis since 1993 and is required to meet the EU control requirements. A control program has been in effect since 1942 but vaccination was voluntary and the disposition of reactors inconsistent. Brucellosis is a significant public health problem in Mexico because 10-25% of milk and cheeses consumed are unpasteurized. As of 2002, about 3500 cases of human brucellosis are reported annually, and it is estimated that this figure represents only one third of the actual cases. About 90% of human cases are infected with B. melitensis. Brucellosis is a significant problem for both public health and animal production in Greece, and a control program consists of vaccination of lambs and kids, and test and slaughter policy. European co-financed eradication programs for sheep and goat brucellosis are in place in France, Greece, Italy, Portugal, and Spain.

**Brucellosis in pigs**

Brucellosis in pigs, especially outdoor-raised pigs, has re-emerged as a result of infection from the wild boar brucellosis reservoir. Each year Mexico imports up to 1 million beef and dairy cattle, and 1 million goats are vaccinated annually; almost 97% of the dairy cattle population is vaccinated.

Canada and the USA

The status of bovine brucellosis in Canada and the USA is presented below under Bovine brucellosis associated with Brucella abortus.

**European Union**

**Bovine brucellosis**

Austria, Denmark, Finland, Germany, the Province Bolzano (Italy), Luxembourg, Norway, Sweden, the Netherlands, and Great Britain have gained the status of being officially brucellosis-free. Countries not officially brucellosis-free are France, Greece, Ireland, Italy, Portugal, and Spain. The prevalence of infection in countries not free of brucellosis is extremely diverse. The highest numbers of infected herds occurred in southern Europe: Greece, Spain, Italy, and Portugal. The prevalence of infection has increased in both the Republic of Ireland and Northern Ireland. Both B. abortus and B. melitensis have been isolated from cattle; B. melitensis may be isolated from cattle in contact with sheep and goats. B. melitensis may cause isolated cases of abortion in cattle rather than outbreaks of abortion.

Great Britain has been free from brucellosis since 1993 and is required to meet the EU control requirements. A control program has been in effect since 1942 but vaccination was voluntary and the disposition of reactors inconsistent. Brucellosis is a significant public health problem in Mexico because 35% of the milk and cheeses consumed are unpasteurized. As of 2002, about 3500 cases of human brucellosis are reported annually, and it is estimated that this figure represents only one third of the actual cases. About 90% of human cases are infected with B. melitensis. Brucellosis is a significant problem for both public health and animal production in Greece, and a control program consists of vaccination of lambs and kids, and test and slaughter policy. European co-financed eradication programs for sheep and goat brucellosis are in place in France, Greece, Italy, Portugal, and Spain.

**Brucellosis in pigs**

Brucellosis in pigs, especially outdoor-raised pigs, has re-emerged as a result of infection from the wild boar brucellosis reservoir. Each year Mexico imports up to 1 million beef and dairy cattle, and 1 million goats are vaccinated annually; almost 97% of the dairy cattle population is vaccinated.

**In the United States**

**REFERENCES**

recognized including a number of strain variants. Approximately 5% of infections are from bioype 1. Bioype 2 was isolated in an outbreak of brucellosis in cattle in Canada in 1986. In the USA bioypes 1–4 are found.

**EPIDEMIOLOGY**

Occurrence and prevalence of infection

Brucellosis is an important disease of cattle and an important zoonosis worldwide. It is of major economic importance in developing countries that have not had a national brucellosis eradication program (see Introduction, above). The prevalence of infection varies considerably among herds, areas, and countries. Many countries have made considerable progress with their eradication programs and some have eradicated the disease. However, in other countries brucellosis is still a serious disease problem facing the veterinary and medical professions. In Argentina, for example, the prevalence of infection in cattle is more than 10% and estimated that 20,000 new cases of human brucellosis occur annually.

Cattle

Infection occurs in cattle of all ages but is most common in sexually mature animals, particularly dairy cattle. Abortions occur most commonly in outbreaks in unvaccinated heifers after the fifth month of pregnancy. Bulls are affected with arthritis, epididymitis, and seminal vesiculitis. The infection has been confirmed in cattle and water buffaloes in Trinidad.3

Wildlife species

The infection has occurred in bison (Bison bison),2 elk (Cervus elaphus canadensis),4 deer, cougars, wild opossums and raccoons, mose and other wild and domesticated ruminants, but there is no evidence that these species are a source of infection for cattle. Infection of moose with B. abortus biovar 1 is highly fatal and it is likely that the moose is a dead-end host for brucellosis. Experimental inoculation of the organism into badgers results in the development of antibodies and elimination of the organism, which indicates that the badger is relatively resistant to infection and unlikely to be a reservoir of the organism.

Bison and elk are potential reservoirs of brucellosis and, because they are the species of choice for game farming, which is a recent development in North America and elsewhere, they could serve as a source of infection for cattle. Brucellosis associated with B. abortus was first detected in bison (Bison bison) in Yellowstone National Park in 1917 and has been present ever since.5 Bison can remain latently infected with virulent B. abortus until attainment of reproductive age despite extensive use of vaccine and serological testing.6

A strain of bioype 1 isolated from bison in Canada is infectious and contagious for cattle. While bovine brucellosis is being effectively eradicated in North America, infected populations of bison, elk, and moose in Canada and the USA are of sufficient size and geographical distribution to create a real and serious threat to the livestock producers in certain areas of both countries.7 B. suis biovar 4 is the cause of rangeliner brucellosis, a disease of reindeer and caribou (Rangifer tarandus).8 Under natural conditions, rangeliner brucellosis is limited to the circumpolar Arctic but translocations to reindeer for game ranching may place traditional livestock species, game-farmed species and non-Arctic wildlife at risk. Naturally infected reindeer can transmit B. suis biovar 4 to brucellosis-free cattle.9 Exposed cattle had a serological response; the organism remained in tissues 60 days after exposure. B. suis biovar 4 does not cause clinically important disease in cattle and is not shed in sufficient numbers to maintain infection in cattle populations. Conventional serological tests can be used to detect B. suis biovar 4 infection, but their ability to detect exposed animals varies widely and they cannot discriminate between B. suis biovar 4 and B. abortus of cattle. Cattle to cattle transmission of B. suis biovar 4 is unlikely.7

In Canada, the wood bison herd in Wood Buffalo National Park has been infected with Mycobacterium bovis and B. abortus since 1925.10 The infected herd poses a potential threat to the nearby MacKenzie Bison Sanctuary, in which these infections are not present.

Horses

In horses the organism is often found in chronic bursal enlargements as a secondary invader rather than a primary pathogen. It is commonly present with Actinomyces bovis in fistulous withers and poll evil. It has also been identified as a cause of abortion in mares. A serological survey of horses over a period of 8 years revealed that 8–16% of serum samples were positive. However, experimentally infected horses do not excrete the organism in sufficient numbers to infect susceptible in-contact cattle.

Pigs and sheep

The organism can be recovered from naturally infected pigs and, although not normally pathogenic in this species, may occasionally cause abortion. The disease occurs naturally in sheep exposed to infected cattle, which has significant implications for brucellosis eradication.

---

**BRUCELLOSIS ASSOCIATED WITH BRUCELLA ABORTUS (BANG’S DISEASE)**

**Etiology**

*Brucella abortus*

**Epidemiology**

Major cause of abortion in cattle in countries without a national control program. Undulant fever in humans an important zoonosis. Sexually mature animals susceptible; outbreaks occur in first-calf heifers, older cows infected but do not abort. Transmitted directly from infected animal to susceptible animal by uterine discharges. Congenital infection occurs. Infection in wildlife species but significance to domestic animals unknown. Infection introduced into herd by unknown infected carrier animal. Natural infection and vaccination result in immunity to abortion but not infection, and infected animals remain serologically positive for a long time.

**Signs**

**Clinical pathology**

**Lesions**

Necrotizing placentitis, inflammatory changes in fetus.

**Diagnostic confirmation**

Culture organism from fetus. Positive serological test in unvaccinated animal.

**Differential diagnosis list**

Other causes of abortion (see Table 18.7)

**Treatment**

No treatment.

**Control**

Test and reduce reservoir of infection. Quarantine. Depopulation. Vaccination to reduce incidence of abortion and percentage of infected animals. Eradication from herd and area basis by test and slaughter.

---

**ETIOLOGY**

*Brucella abortus* is the causative organism and at least nine biotypes have been
Dogs
Naturally acquired B. abortus infection can occur in dogs associated with infected cattle. While farm dogs are not generally considered to be a major reservoir of B. abortus, the organism has been isolated from dogs on a farm where several cattle were serologically positive for brucellosis and dogs should be included in any investigation and eradication of the disease.

Methods of transmission

Parturition
The risk posed to susceptible animals following parturition of infected cattle depends on three factors:

- The number of organisms excreted
- The survival of these organisms under the existing environmental conditions
- The probability of susceptible animals being exposed to enough organisms to establish infection.

The organism achieves its greatest numbers in the contents of the pregnant uterus, the fetus and the fetal membranes, all of which must be considered as major sources of infection. The numbers of organisms in the tissues of two naturally infected cows and their fetuses were as follows: umbilicus 2.4 x 10⁶ - 4.3 x 10⁹/g, uterine discharges 1.4 x 10¹⁰/g. This illustrates the potentially large numbers of organisms that can be shed and to which other animals and humans are potentially exposed. However, the numbers of organisms decrease when uterine discharges are cultured at sequential parturitions, and a substantial number of uterine samples from infected cows are culture-negative at the second and third parturition following challenge.

Transmission
The disease is transmitted by ingestion, penetration of the intact skin and conjunctiva, and contamination of the udder during milking. The organism does not multiply in the environment but merely persists, and the viability of the organism outside the host is influenced by the existing environmental conditions. Grazing on infected pasture, or consuming other feedstuffs and water supplies contaminated by discharges and fetal membranes from infected cows, and contact with aborted fetuses and infected newborn calves are the most common methods of spread.

Intraherd spread occurs by both vertical and horizontal transmission. Horizontal transmission is usually by direct contamination and, although the possibility of introduction of infection by flies, dogs, rats, ticks, infected boots, fodder, and other inanimate objects exists, it is not significant relative to control measures. The organism is ingested by the face fly but is rapidly eliminated and there is no evidence for a role in natural transmission. Evidence exists for horizontal, dog-to-dog, cattle-to-cattle, dog-to-cattle and dog-to-human transfer of infection. The most likely and effective means of cattle-to-cattle transfer is exposure to aborted fetuses or infected placental membranes, because dogs commonly ingest the products of parturition.

Spread between herds
Movement of an infected animal from an infected herd to a susceptible noninfected herd is a common method of transmission. The rate of spread will depend on the level of surveillance testing. In Great Britain, which is officially brucellosis free, 20% or more of both beef and dairy cattle more than 24 months old are tested routinely. A simulation model indicates that reducing the level of testing would have a major effect on the rate of spread of infection, should it be imported.

Spread between countries (breach of biosecurity)
A quantitative risk assessment model to determine the annual risk of importing brucellosis-infected breeding cattle into Great Britain from Northern Ireland and the Republic of Ireland, which are not brucellosis free, was developed. Predictions estimated that brucellosis could be imported from Northern Ireland every 2.63 years and from the Republic of Ireland every 3.23 years. Following this assessment, the Department of Environment, Food and Rural Affairs introduced postcalving testing for all imported breeding cattle. Under this system, all imported animals are issued a passport that records their age and pregnancy status. This information enables identification of animals that require testing and provides an additional safeguard in maintaining official brucellosis status.

Congenital infection
Congenital infection may occur in calves born from infected dams but its frequency is low. The infection occurs in utero and may remain latent in the calf during its early life; the animal may remain serologically negative until its first parturition, when it then begins to shed the organism. Calves born from reactor dams are serologically positive for up to 4-6 months because of colostal antibodies and later become serologically negative even though a latent infection may exist in a small proportion of these calves. The frequency of latent infections is unknown, but may range from 2.5-9%. Latent infections in serologically negative animals are of some concern because they remain unnoticed and can potentially serve as a source of infection later. However, latent infections in calves born from infected cows are infrequent. The organism could not be isolated from any of 150 calves born to infected cows, 135 of which were experiencing their first pregnancy after infection. In one report a heifer from a herd infected with widespread infection with B. abortus biotype 2 was moved to a brucellosis-free herd and remained apparently free from brucellosis until 9 years later, when the same animal produced a strongly positive serological reaction and the same biotype was isolated from its milk. Such observations have resulted in the recommendation that calves from seropositive dams should not be used for breeding. Even vaccinated heifers from seropositive dams can harbor a latent infection. There is a risk that 2.5% of heifer calves born from serologically positive dams will react in early adulthood and constitute a threat to a re-established herd.

Survival of organism
The organism can survive on grass for variable periods depending on environmental conditions. In temperate climates, infectivity may persist for 100 days in winter and 30 days in summer. The organism is susceptible to heat, sunlight, and standard disinfectants but freezing permits almost indefinite survival. The activity of several disinfectants against B. abortus has been examined, and representatives of the phenolic, halogen, quaternary ammonium, and aldehyde groups of disinfectants at 0.5% or 1.0% concentrations in the absence of serum generally inhibited a high concentration of the organism.

Uterine discharges and milk
A cow's tail heavily contaminated with infected uterine discharges may be a source of infection if it comes in contact with the conjunctiva or the intact skin of other animals. In the same way that the more common forms of mastitis can be spread during milking, B. abortus infection can be spread from a cow whose milk contains the organism to an uninfected cow. This may have little significance in terms of causing abortion but it is of particular importance in its effects on agglutination tests on milk and the presence of the organism in milk used for human consumption.

Bulls and semen
Bulls do not usually transmit infection from infected cows mechanically. Infected bulls may discharge semen containing organisms but are unlikely to transmit the infection. The risk of spread from the bull is much higher, however, if the semen is used for artificial insemination. Some infected bulls are
negative on serum agglutination tests and their carrier status can only be detected by the isolation of organisms from the semen or agglutination tests on seminal plasma.

Carrier cows
Few infected cows ever recover from infection completely and should be considered as permanent carriers whether or not abortion occurs. Excretion of the organism in the milk is usually intermittent, is more common during late lactation and can persist for several years. In cattle vaccinated before infection the degree of excretion of B. abortus in the milk is less than in nonvaccinated animals. Embryo transfer from infected donors may be achieved without transfer of infection and superovulation is unlikely to reactivate the release of Brucella into the uterus during the period when embryos are normally collected. Thus embryo transfer is a safe procedure for salvaging genetic material from infected animals.

The herd characteristics and the results of the first herd test may be used as predictors of the potential presence or absence of B. abortus in herds with reactors to the tub test agglutination test. The presence of only single suspicious reactors on the first test is a reliable predictor of lack of infection. The presence of one or more positive reactors on the first herd test is a reliable predictor of the presence of infection.

Risk factors
The risk factors that influence the initiation, spread, maintenance, and/or control of bovine brucellosis are related to the animal population, management, and the biology of disease. The variables that contribute significantly to seropositive animals are:

- **Size of farm premises**
- **Percentage of animals on a premises that are inseminated artificially**
- **Size of investment in livestock**
- **Number of cows which aborted in the previous year, whether or not dairying is the major agricultural activity of the premises**
- **Policy of the owner with regard to disposal of reactor animals.**

The longer infected animals are in contact with the remainder of the herd, the greater will be the ultimate number of seropositive animals. In a defined geographical area in northern Mexico where a brucellosis control program did not exist, the greatest percentage of seropositive animals was related to larger farms, poor artificial insemination technique, and small financial investment in the farm.

From a practical viewpoint, the factors influencing the transmission of brucellosis in any given geographical region can be classified into two fundamental categories: those associated with the transmission of disease between herds and those influencing the maintenance and spread of infection within herds. Factors influencing interherd transmission include the purchase of infected replacement animals and are in turn influenced by frequency of purchase, source of purchase, and brucellosis test history of purchased animals. The proximity of infected herds to clean herds is an important risk factor. Cattle contacts at fence lines, sharing of pastures and strays of infected animals into clean herds are common methods by which transmission occurs to adjacent herds.

The risk factors associated with spread of the disease within a herd include unvaccinated animals in infected herds, herd size, population density, method of housing, and use of maternity pens. Large herd sizes are often maintained by the purchase of replacement cattle, which may be infected. It is also more difficult to manage large herds, which may lead to managerial mistakes that allow the disease to spread. There is a positive association between population density (number of cattle to land area) and disease prevalence, which is attributed to increased contact between susceptible and infected animals. The use of maternity pens at calving is associated with a decrease in the prevalence of infection, presumably due to decreasing the exposure of infected and susceptible animals.

Animal risk factors
Susceptibility of cattle to B. abortus infection is influenced by the age, sex, and reproductive status of the individual animal. Sexually mature, pregnant cattle are more susceptible to infection with the organism than sexually immature cattle of either sex. Natural exposure to field strains occurs primarily at the time of parturition of infected cows. The greater the number of infected cows that abort or calve, the greater the exposure risk to the other cattle in the herd. An important application of this observation is that infected cows need to be removed from the herd prior to parturition. Thus the stage of gestation and parturition are more important factors in herd plans than early removal of postparturient infected cows following whole-herd strain-19 vaccination. Young cattle are less susceptible to B. abortus than older, sexually mature cattle. Susceptibility appears to be more commonly associated with sexual maturity than age. Young, sexually immature cattle generally do not become infected following exposure, or recover quickly. Susceptibility increases with pregnancy and as the stage of gestation increases.

The probability of isolation of the organism at parturition increased from 0.22 to 0.90 as fetal age at exposure of nonvaccinated heifers increased from 60 to 150 gestation days. The stage of pregnancy at experimental challenge exposure of strain-19 vaccinated heifers is positively associated with the proportion of animals that become infected. Nonvaccinated young cattle are also at high risk of brucellosis if exposed to pathogenic strains of the organism. In cattle vaccinated as yearling heifers, the risk of brucellosis is also related to the number of organisms in the vaccine. The risk of brucellosis in heifers vaccinated with 10^6, 10^7, or 10^8 of strain 19 was, respectively, one-third, one-seventh, or one-tenth of that of diluent controls or nonvaccinated heifers.

**Management risk factors**

The spread of the disease from one herd to another and from one area to another is almost always due to the movement of an infected animal from an infected herd into a noninfected susceptible herd. The unregulated movement of cattle from infected herds or areas to brucellosis-free herds or areas is the major cause of breakdowns in brucellosis eradication programs.

A case-control study of brucellosis in Canada indicated that herds located close to other infected herds and those herds whose owners made frequent purchases of cattle had an increased risk of acquiring brucellosis. Once infected, the time required to become free of brucellosis was increased by large herd size, by active abortion, and by loose housing.

**Pathogen risk factors**

B. abortus is a facultative intracellular parasite capable of multiplication and survival within host phagocytes. The organisms are phagocytosed by polymorphonuclear leukocytes in which some parasites multiply and replicate in the host. The probability of isolation of the organism at parturition increased from 0.22 to 0.90 as fetal age at exposure of nonvaccinated heifers increased from 60 to 150 gestation days. The stage of pregnancy at experimental challenge exposure of strain-19 vaccinated heifers is positively associated with the proportion of animals that become infected. Nonvaccinated young cattle are also at high risk of brucellosis if exposed to pathogenic strains of the organism. In cattle vaccinated as yearling heifers, the risk of brucellosis is also related to the number of organisms in the vaccine. The risk of brucellosis in heifers vaccinated with 10^6, 10^7, or 10^8 of strain 19 was, respectively, one-third, one-seventh, or one-tenth of that of diluent controls or nonvaccinated heifers.

**Management risk factors**

**Pathogen risk factors**

B. abortus is a facultative intracellular parasite capable of multiplication and survival within host phagocytes. The organisms are phagocytosed by polymorphonuclear leukocytes in which some parasites multiply and replicate in the host.

Brucella abortus is a facultative intracellular parasite capable of multiplication and survival within host phagocytes. The organisms are phagocytosed by polymorphonuclear leukocytes in which some parasites multiply and replicate in the host.
Brucellas are able to survive within host leukocytes and may utilize both neutrophils and macrophages for protection from humoral and cellular bacterial mechanisms during the periods of hematogenous spread. The placenta is a favored site for replication of the organism. Large numbers of the organism can be found in choriionic trophoblasts, which contain metabolically active cells capable of producing a variety of hormones and secretory proteins that may stimulate the growth of brucellas. The ability to survive in the host may explain both the transitory titers occurring in some animals following isolated episodes of bacteremia and the disappearance of titers in animals with latent infection.

Three major groups of outer membrane proteins have been identified in *Brucella* spp. Certain mutants of *B. abortus* lack a major 25 kDa outer membrane protein (Omp25), which renders them unable to replicate efficiently in bovine phagocytes and choriionic trophoblasts.

**Immune mechanisms**

Immunity against brucellosis is principally mediated by cellular immune responses since it is an intracellular pathogen. *B. abortus* is an efficient inducer of type 1 cellular immune responses and interferon-gamma is crucial for control of brucellosis. Infections are chronic and often lifelong. The bovine T lymphocyte in brucellosis is a critical component of host defense based on mononuclear phagocyte activation by interferon-gamma. The killing of *Brucella*-infected mononuclear phagocytes and interferon-gamma-mediated activation of mononuclear phagocytes are the major mechanisms of host defenses against brucellosis in cattle.

The antibody response to *B. abortus* in cattle consists of an early IgM isotype response, the timing of which depends on the route of exposure, the dose of the bacteria and the health status of the animal. The IgM response is followed almost immediately by production of IgG1 antibody and later by small amounts of IgG2 and IgA. Most cross-reacting antibody from exposure to other bacteria other than *Brucella* spp. or environmental antigens consists mainly of IgM. Serological tests that measure IgM are therefore not desirable, as false-positive results occur. Since IgG2 and IgA antibodies accumulate later after exposure and are usually present in small and inconsistent amounts, the main isotype for serological testing is IgG1.

Naturally infected animals and those vaccinated as adults with strain 19 remain positive to the serum, and other agglutination tests, for long periods. The serum of infected cattle contains high levels of IgM, IgG1, IgG2, and IgA isotypes of antibody. Most animals vaccinated between 4 and 8 months of age return to a negative status to the test within a year. All are considered to have a relative immunity to infection. Calves from cows that are positive reactors to the test are passively immunized via the colostrum. The half-life of colostral antibodies to *B. abortus* in calves that have received colostrum from either vaccinated noninfected or infected dams is about 22 days. It is possible that some calves remain immune sufficiently long to interfere with vaccination. After vaccination of cattle with strain 19 of the organism, IgM antibodies appear after about 5 days, reaching peak values after 13 days. IgG1 antibodies appear a little later or simultaneously with IgM, and peak values are reached at 28–42 days, after which they decline. The same general pattern follows experimental infection with virulent strains and also in chronic field cases, except that IgM antibody declines to low levels and residual activity resides in IgG1 and IgG2 as well as in IgA, which remain at higher levels.

**Economic importance**

Losses in animal production due to this disease can be of major importance, primarily because of decreased milk production in aborting cows. The common sequel of infertility increases the period between lactations, and in an infected herd the average intercalving period may be prolonged by several months. In addition to the loss of milk production, there is the loss of calves and interference with the breeding program. This is of greatest importance in beef herds, where the calves represent the sole source of income. A high incidence of temporary and permanent infertility results in heavy culling of valuable cows, and some deaths occur as a result of acute metritis following retention of the placenta.

**Zoonotic implications**

Brucellosis is an important zoonosis causing undulant fever in humans. According to the Food and Agriculture Organization, the World Health Organization and the Office International des Epizooties, brucellosis is still one of the most important and widespread zoonoses in the world. The disease spreads mainly by the ingestion of unpasteurized dairy products. Officially approved methods of commercial pasteurization render naturally *Brucella*-contaminated raw milk safe for consumption. However, most cases in humans are occupational and occur in farmers, veterinarians, and butchers. The organism can be isolated from many organs other than the udder and uterus, and the handling of a carcass of an infected animal may represent severe exposure.

The importance of the disease in humans is an important justification for its eradication. Between the years 1965 and 1974 the incidence of brucellosis in humans in the USA increased. Most cases occur in people employed in the meat processing industry, while other sources include the domestic pig, cattle, and unpasteurized dairy products. A majority of human brucellosis cases in Texas could be prevented by prohibiting the importation of unpasteurized goat's milk cheese. Laboratory-acquired brucellosis in humans constituted 1.7% of the cases of brucellosis reported in the USA between 1964 and 1974.

The cost-effectiveness to human health and the potential net economic benefits of a nationwide mass vaccination program for livestock over a period of 10 years has been evaluated using Mongolia as the model. If the costs of vaccination of livestock against brucellosis were allocated to all sectors in proportion to the benefits, the intervention would be cost-effective and would result in net economic benefits.

**PATHOGENESIS**

*B. abortus* has a predilection for the pregnant uterus, udder, testicle and accessory male sex glands, lymph nodes, joint capsules, and bursae. After the initial invasion of the body, localization occurs initially in the lymph nodes draining the area and spreads to other lymphoid tissues, including the spleen and the mammary and iliac lymph nodes.

*B. abortus* is phagocytized by macrophages and neutrophils in an effort by the host to eliminate the organism. However, once inside the phagocyte, *B. abortus* is able to survive and replicate. The phagocyte migrates via the lymphatic system to the draining lymph node, where *Brucella* infection causes cell lysis and eventual lymph node hemorrhage 2–3 weeks following exposure. Because of vascular injury, some of the bacteria enter the bloodstream and subsequently bacteremia occurs, which disseminates the pathogen throughout the body. If the infected animal is pregnant, *B. abortus* will colonize and replicate to high numbers in the choriionic trophoblasts of the developing fetus. The resulting tissue necrosis of the fetal membranes allows transmission of the bacteria to the fetus. The net effect of chorionic and fetal colonization is abortion during the last trimester of pregnancy.

Sexually immature and nonpregnant cattle can become infected but lose their humoral antibody to the organism much more quickly than cattle infected while pregnant.
In the adult, nonpregnant cow, localization occurs in the udder, and the uterus, if it becomes gravid, is infected from periodic bacteremic phases originating in the udder. Infected udders are clinically normal but they are important as a source of reinfection of the uterus, as a source of infection for calves or humans drinking the milk, and because they are the basis for the agglutination tests on milk and whey.

Erythritol, a substance produced by the fetus and capable of stimulating the growth of B. abortus, occurs naturally in greatest concentration in the placental and fetal fluids and is responsible for localization of the infection in these tissues. Invasion of the gravid udder results in a severe ulcerative endometritis of the intercotyledonary spaces. The allantochorion, fetal fluids, and placental cotyledons are invaded and the villi are destroyed. The organism has a marked predilection for the ruminant placenta. In acute infections of pregnant cows, up to 85% of the bacteria are in cotyledons, placental membranes, and alantoic fluid.

The successful coexistence of Brucella spp. with its preferred host is the outcome of coevolutionary relationships and selection pressures, which result in a stalemate where the pathogen has evolved to survive within the biological system of the host, and the host has evolved innate and acquired immune systems that allow controlled survival of infection by the pathogen, ultimately supporting the survival of the host–pathogen system. In contrast to other pathogens, genes controlling virulence, survival and persistence of Brucella spp. have been documented as the dominant feature of its genome.

The host responses at the organ and tissue levels have been described and are summarized here. Lymph nodes draining the sites of the early stages of infection have marked germinal center hyperplasia and hypertrophy, accompanied by acute neutrophilic and eosinophilic lymphadenitis. In the later stages of the infection, lymph nodes draining mammary gland, head, and reproductive tract develop chronic granulomatous lymphadenitis, which is usually associated with cortical and paracortical T-cell-dependent lymphoid degeneration, germinal center expansion, and deep histiocytic expansion. The spleen may develop lymphoid hyperplasia and histiocytic and plasmacytic expansion in the germinal centers, and the mammary gland usually has a pronounced interstitial lymphoplasmacytic mastitis. In the uterus, there is usually an endometritis, fibrosing mural lymphohistiocytic metritis, and caruncular necrotizing vasculitis, while the placenta is colonized with B. abortus and has extensive desquamation of fetal chorioallantoic trophoblasts with subsequent hematogenous spread to villous trophoblastic epithelium, and necrotizing fibrinopurulent cotyledonal placenditis of the placental arcades accompanied by granulation and intercotyledonary inflammation exudation. The fetal lesions consist of marked fibrinopurulent necrotizing bronchopneumonia, mononuclear and neutrophilic alveolitis, thromboembolic necrotizing arteritis and lymphangitis, fibrinopurulent pleuritis, and granulomata of the liver, spleen, kidney, and lymph nodes.

Variable disease expression may occur in the male reproductive tract and musculoskeletal system of either sex. The affected joints usually develop a fibrinous and granulomatous synovitis with proliferative villous projection formation, proliferative tendovaginitis with lymphoplasmacytic nodule formation, and arthritis with articular erosions, which may be associated with supplicative, granulomatous bursitis. In the testes there are uni- or bilateral vesical to parietal tunica adhesions, interstitial lymphocyte orchitis with seminiferous tubular degeneration, necrotizing intratubular orchitis, and acute fibrinopurulent periorchitis with infarction. The ampulla may have a uni- or bilateral granulomatous epididymitis with focally necrotic purulent, calcified sperm granulomata and the seminal vesicles have uni- or bilateral necrotizing fibrinopurulent seminal vesiculitis and interstitial lymphocytic, plasmacytic seminal vesiculitis with necrosis.
